SYMPOSIUM ON NEUROPSYCHIATRIC DISEASES

ACUTE ENCEPHALO MYELO RADICULONEURITIS (GUILLAIN BARRÉ SYNDROME)

ROLAND P. MACKAY, M.D.*

WE have for presentation and discussion today three cases representing a neurologic condition apparently quite common, and yet frequently not recognized. Many more cases could be presented, but these three suffice to illustrate variant forms of the disorder.

CASE I—O. D. a white, unmarried man aged 40, was admitted to the Illinois Neuropsychiatric Institute on March 30, 1944, complaining of "sinus trouble" and deviation upward of the left eye for six weeks and weakness of all the extremities of the body for two weeks. About February 20 he had had a "cold" with nasal obstruction and some swelling of the left cheek. A week later the left eye had turned upward and paralysis of the left side of the face was noted. About two weeks later numbness of the left side of the face had appeared, with weakness of the right arm.

He was then (March 20) admitted to the service of Dr. Paul Bucy at the Chicago Memorial Hospital where examination revealed marked weakness of the left inferior rectus muscle, the left side of the face and weakness of abduction of the right arm together with slight impairment of sensibility to pain and touch over the left side of the face. His temperature was normal and his blood pressure 168/112. The spinal fluid was clear and colorless and under a pressure of 130 mm. of water. The cell count was zero and total protein content 80.

From the Department of Neurology and Neurological Surgery, University of Illinois College of Medicine, and the Illinois Neuropsychiatric Institute, Chicago.
Professor of Neurology, University of Illinois College of Medicine.

mg per 100 cc Gold curve was 0033310000 X-rays revealed clouding of the left frontal, ethmoid and maxillary sinuses, and apical infection of a lower molar tooth A day after discharge from the Chicago Memorial Hospital the patient noted weakness of both lower extremities and tingling paresthesias in all four extremities

On March 30, *examination* at the Illinois Neuropsychiatric Institute revealed weakness of outward and downward gaze of the left eye The left pupil was larger than the right, and both were sluggish to light and in accommodation There was weakness of the left side of the face and deviation of the uvula toward the right on phonation There was also muscular weakness of all four extremities, chiefly proximal All deep tendon reflexes were absent, and the abdominal reflexes were doubtfully present The Babinski responses were normal Superficial sensation was all normal except for slight hyperesthesia below the left eye Vibratory sensation was diminished and proprioceptive sensation lost in the lower extremities The muscles of the extremities were tender Within the next few days his condition deteriorated, with weakness spreading to involve the left sternomastoid and trapezius muscles The sphincters functioned normally

Laboratory examination of the urine and blood gave only normal findings The spinal fluid was examined five times The results are shown in the following table On all occasions the fluid was clear and colorless, with normal pressure and response to jugular compression

Date	Cells	Pandy Test	Total Protein, Mg per 100 Cc	Sugar, Mg per 100 Cc	Chlorides, Mg per 100 Cc	Wassermann Test	Gold Reaction

5/23	2	2 "	220	63			0000023432
6/29	3	1 "	170				

This patient remained in the hospital for three months During the first portion of his stay his neurological abnormalities increased Vibratory and proprioceptive sensibility decreased in the upper extremities, and his dysphonia and dysphagia continued Respirations were seriously embarrassed He was treated with large amounts of vitamins B and C and crude liver extract Physiotherapy was also administered in the form of heat, massage and exercises Suddenly, on June 12 he improved abruptly and thereafter gained ground rapidly He was able to walk on June 18, and on June 30 he was discharged with instructions to continue to take vitamins orally His diplopia, due to persisting weakness of the left oculomotor nerve, was still present, though diminished when he left

In this case a healthy man, after an upper respiratory infection developed an extensive polyneuritis with involvement of cranial as well as spinal nerves and markedly elevated total protein content of the spinal fluid without increase of the cell count. Though delayed recovery came in four months after the onset, and was practically complete. Note that in this case the elevated protein content of the cerebrospinal fluid gave indication of inflammatory change in the spinal and cranial nerve roots, but there was no clear evidence of pathologic change within the brain or spinal cord. The level of total protein in the cerebrospinal fluid rose during the first part of his stay in the hospital, and later declined, but was still quite high when he left the hospital almost well.

In the following case a very similar series of events is seen.

CASE II—O. W., a colored married man, aged 44, was admitted to the Illinois Neuropsychiatric Institute on May 14, 1944, complaining of progressive weakness of his extremities for twelve days and difficulty in swallowing, and hoarseness for three days. Four weeks previously he had contracted a cold with aching pains in his back and legs. Twelve days before admission he had noted weakness and sharp pains in his extremities.

The diagnosis of polyneuritis had been made by Dr. Paul Bucy upon the patient's admission to the Chicago Memorial Hospital on May 5, 1944. There the cerebrospinal fluid contained 42 mg. of total protein per 100 cc., with 3 cells per cubic millimeter (see accompanying table). The weakness in his lower extremities increased with additional paresthesias after his return home. Dysphonia and dysphagia began three days before admission.

General *examination* revealed a temperature of 101° F., a pulse rate of 128, and respirations of 28. He was coughing up much sputum and presented signs of pneumonia in the right upper lobe. Neurologically he was hoarse and unable to swallow. There was marked weakness in the upper extremities and complete paralysis of the lower, worse proximally. Beevor's sign was present. All deep reflexes were absent, the abdominal reflexes were diminished and there was no response to plantar stimulation. Vibratory sensibility was absent in both lower extremities and diminished in the right upper. Superficial sensibility was reduced over the feet, calves and posterior portions of the thighs. The muscles of the extremities were tender.

Laboratory studies were normal except for a leukocyte count of 24,250, a figure which steadily declined to 10,100 within two weeks. Additional spinal punctures gave the findings shown in the table. One should note the increased content of total protein with normal cell count. On all occasions the fluid was clear and colorless with normal pressure and dynamics.

mg per 100 cc Gold curve was 0033310000 X-rays revealed clouding of the left frontal, ethmoid and maxillary sinuses, and apical infection of a lower molar tooth A day after discharge from the Chicago Memorial Hospital the patient noted weakness of both lower extremities and tingling paresthesias in all four extremities

On March 30, *examination* at the Illinois Neuropsychiatric Institute revealed weakness of outward and downward gaze of the left eye The left pupil was larger than the right, and both were sluggish to light and in accommodation There was weakness of the left side of the face and deviation of the uvula toward the right on phonation There was also muscular weakness of all four extremities, chiefly proximal All deep tendon reflexes were absent, and the abdominal reflexes were doubtfully present The Babinski responses were normal Superficial sensation was all normal except for slight hyperesthesia below the left eye Vibratory sensation was diminished and proprioceptive sensation lost in the lower extremities The muscles of the extremities were tender Within the next few days his condition deteriorated, with weakness spreading to involve the left sternomastoid and trapezius muscles The sphincters functioned normally

6/5	3	1 "			0000122110
6/16	4	1 "	180		

Blood culture on admission gave hemolytic *Staphylococcus aureus*, and culture of the sputum showed a pure growth of *Pseudomonas albuginosa*.

Course The patient was given sulfadiazine by mouth and a diet high in calories and vitamins. Crude liver extract and high doses of ascorbic acid, thiamine hydrochloride and niacinamide were given every day intramuscularly. The pneumonia gradually cleared but respiratory paralysis increased markedly so that the use of a respirator was seriously considered. On May 22 both respiration and swallowing improved rapidly and motor strength increased, first in the upper and then in the lower extremities. By July 22 the patient was able to walk with some weakness, and was discharged.

Again, we note the occurrence of an upper respiratory infection followed in about two weeks by the onset of paralytic disorders. Here, the weakness appeared first in the lower extremities, in the first case certain of the cranial nerves were primarily affected. The onset of the paralysis in the second case was soon followed by bronchopneumonia which was mild and rapidly responded to treatment with sulfadiazine. The extreme degree of paralysis of the lower motor neuron may have masked reflex evidences of implication of the central nervous system, but at any rate no such evidences were found.

In the third and final case to be presented a much more severe and persistent neurologic disturbance may be seen. The clinical involvements were far more extensive, and differed somewhat from those observed in the first two cases, but sufficient similarity existed for us to recognize the same general type of disease.

CASE III—G. L., a white, married woman, aged 40, with two children, was admitted to St. Luke's Hospital in Chicago on April 1, 1944, complaining of marked weakness of the left arm, "numbness" of both arms and the left leg, and pains in the neck and shoulder for three weeks.

Early in January she had had anorexia, and on January 20 had felt ill, had a slight fever, and vomited. For two weeks thereafter she had hiccoughs intermittently. Early in March she began to have pain

in the left shoulder and arm, and soon this pain extended to involve, in order, the left lower, the right lower, and the right upper extremities. There was a sense of compression in the left side of the thorax and abdomen. The pain was a dull ache with occasional sharp stabs, subsiding to leave an itching sensation. Within a few days numbness began in all extremities, particularly on the left.

About March 22 weakness appeared in the left upper and lower extremities and grew worse. She could no longer tell where the left forearm was. Pains, drawing sensations and feelings of tightness continued.

Examination on admission revealed an emaciated woman, with normal cranial nerves. The left upper extremity was moderately weak and atrophy had produced a *main en griffe* deformity in the left hand. Occasional athetoid movements were seen in this hand. There was slight weakness in the left lower extremity. The tendon reflexes were markedly reduced in both left extremities and the right ankle jerk was barely elicitable. Abdominal reflexes were absent on the left and sluggish on the right. The Babinski reflex was positive on the left and equivocal on the right. Sensibility to pain, touch, heat and cold was reduced in the left upper extremity and over the upper half of the thorax on the left. Both vibratory and position sensibility was markedly reduced in the whole left upper extremity, with complete stereo-anesthesia. Vibratory sensibility was moderately reduced in both ankles. There was definite tenderness in the calves and shoulders and in the left arm.

Laboratory studies The Kahn test of the blood was negative. Erythrocytes numbered 3,720 million, leukocytes 5,100, and hemoglobin content was 11.3 gm per 100 cc. Gastric analysis revealed 20 units of free acid, 5 of combined acid.

Cerebrospinal fluid was clear and colorless and under pressure of 96 mm of water, with normal dynamics. The total protein content was elevated to 50 mg per 100 cc. The cell count was 25 (see table). Three days later a second spinal picture showed no cells and total protein of 30 mg per 100 cc. Roentgenograms revealed slight osteoarthritis of the cervical spine.

Date	Cells	Pandy Test	Total Protein Mg per 100 Cc	Wassermann Test	Gold Reaction
4/4	25	2 plus	50	Negative	0001100000
4/7	0	1	30		1123331000
5/11	10	1	45		1122321000
5/24	0		50		0012231100

The patient remained practically afebrile. Some weakness began to appear also in the right arm. Three intravenous injections of typhoid

vaccine gave temperatures of 102.6°, 101.8°, and 100.6° F respectively, and no clinical change. She was treated with niacinamide and thiamine hydrochloride in doses of 100 mg each, daily. Because of the expense of hospitalization, she was discharged on April 17.

Interval history At home the patient had severe night sweats, the right arm became weaker, the left a little stronger. She experienced frontal headaches and muscular cramps in both legs.

Rehospitalization The patient was rehospitalized on May 9 in the Illinois Neuropsychiatric Institute. Neurologic examination revealed essentially unchanged findings except for slight inequality of the pupils, weakness of the sternomastoid muscles, and definitely more marked paresis of the right arm and leg. During her stay in this hospital there was slow improvement in the power of the left upper extremity. The legs became slightly spastic with increased knee and ankle jerks. The cerebrospinal fluid was examined on two occasions, and showed slightly elevated protein content without increased cell count (see table). Cramps continued in the lower extremities despite administration of calcium and phenobarbital. Multiple vitamin preparations were given parenterally in large doses, as well as crude liver extract. Physiotherapy included heat, massage and muscle reeducation. The patient was allowed to return home on July 22 still unable to walk, still not greatly improved above her condition on admission.

In this unusual case we note an onset with vague symptoms suggesting encephalitis, with vomiting and hiccoughs, followed by pains, paresthesias and weakness in first the left upper, then the left lower, then the right lower, and finally the right upper extremity. There were indubitable evidences of involvement of the central nervous system, such as the marked loss of proprioceptive and vibratory sensibility in the left arm, the mild athetosis in the left hand, the gradually increasing spasticity in the lower extremities and the pathologic Babinski responses. Yet the paresthesias, pains and tenderness, as well as the atrophy indicated disturbances in the nerves and roots. The cranial nerves escaped all but minor damage. The cerebrospinal fluid vaguely suggested elevation of total protein without increase of cells, but not strongly. Finally, the patient failed to make more than slight improvement during over four months of illness, despite intensive hospital management.

COMMENT

In the first two cases one must diagnose the condition as acute infectious radiculoneuritis with albuminocytologic dissociation. In the third the diagnosis must be acute infectious encephalo-myelo-radiculoneuritis with a tendency to albuminocytologic dissociation. Reference to other cases which might have been reported, and to numerous

cases in medical literature, indicates that our three patients suffered from a condition of considerable variability and pleomorphism, and yet characterized by some combination of signs and symptoms of which our third patient presented almost the complete catalog.

Historical—Although previous reports had been made, Osler, in 1892, first definitively described "acute infectious polyneuritis." Mills, in 1898, used the term "neuritis" for the first time. In 1916 Patrick noted the frequent occurrence of facial paralysis in association with acute polyneuritis. In the same year 1916, Guillain, Barré and Strohl first drew attention to the tendency in the cerebrospinal fluid toward elevation of the total protein with little or no increase in the cell content, the so-called albuminocytologic dissociation. Shortly thereafter a number of other reports appeared, including one by Bradford, Bashford and Wilson in 1918, in which evidence was presented for the virus etiology of this disease though their results could never be confirmed. Recent worthy reviews are those of De Jong in 1940 and Roseman and Aring in 1941.

Definition—Acute infectious encephalo-myeo-radikuloneuritis is an acute, pleomorphic disease of the nervous system, usually following an upper respiratory infection, and characterized by paresthesias and pains, widespread neuritic motor weakness of the extremities and frequently involving the seventh or other cranial nerves and sometimes the cerebrospinal axis and often associated with elevation of the total protein content of the cerebrospinal fluid without significant increase of the cell content. The unwieldy name results from the potential involvement of the brain, spinal cord, nerve roots and peripheral nerves. In many cases one or more of these features may be absent, the brain and spinal cord frequently escaping injury as judged by the clinical features. In a varying percentage of cases (14 to 42 per cent) death follows in the acute stage but in the majority complete recovery is achieved after several weeks or months, although persistent neurologic damage has been recorded in some cases, as in our Case III.

Clinical Features—Any age group may be attacked. The outstanding neurologic features are the paresthesias and pains, the motor weakness of the lower neuron type, and the diminution or loss of the tendon reflexes. Tenderness of the affected muscles may be striking. Paralysis of the face on one or both sides is not uncommon, and other cranial nerves are only less frequently involved. Invasion of the spinal cord or brain may be indicated by the presence of pathologic reflexes, mental abnormalities, hyperkinesias or papilledema. The presence of albuminocytologic dissociation is observed in more than half of the cases. Sphincters are usually spared. Although the onset and invasion

of the disease are usually acute, recovery may be prolonged. Etiology is unknown, but the disease is generally supposed to be due to a virus.

Pathologic Features—The chief pathologic abnormalities are degeneration of the roots and peripheral nerves, sometimes with cellular infiltrations, and congestion of the nerves and often of the spinal cord. Cellular degenerations reported in the neuraxis have regularly been mild or doubtful, but those in the dorsal root ganglia indisputable.

Diagnosis—Diagnosis is not difficult if one requires the presence of more than one or two of the clinical features. Poliomyelitis may cause some difficulty, but the presence of sensory changes and the frequent albuminocytologic dissociation should serve to distinguish the disease under discussion. Albuminocytologic dissociation alone is not sufficient for the diagnosis, since it may be absent, or may be found in other forms of polyneuritis, such as postdiphtheritic type. Polyneuritis of other types are to be distinguished by the history, the absence of albuminocytologic dissociation, and the absence of features suggesting involvement of the neuraxis. Landry's ascending paralysis—an unfortunate term signifying cephalad progression—may be caused by the disease under discussion, but it may also be caused by poliomyelitis, thrombosis of the anterior spinal artery and probably other conditions as well.

Treatment—Treatment must be only symptomatic until more is known of the cause of the disease. Vitamin B should be given in abundance, with careful nursing directed to the prevention of bed-sores and adequate nutrition. Respiratory paralysis may require the use of a respirator. Physiotherapy may be very useful after the acute stage in the prevention of contractures and the restoration of maximal muscular function.

THE DIAGNOSIS AND SURGICAL TREATMENT OF PERIPHERAL NERVE INJURIES

LOYAL DAVIS, PH D, M D, D Sc.*

DEJERINE, a great French neurologist, once said, "Nerve wounds are still a mysterious disturbing problem to many doctors' Injuries to peripheral nerves in civil life are sufficiently infrequent so that no one individual has been able to gather enough personal cases to make a thoroughly profitable clinical investigation As a result, the greater part of our knowledge concerning these injuries has come from World War I and prior to that, the Civil and Russo-Japanese Wars

Unfortunately however, much of the clinical work that was done upon peripheral nerve injuries in the last war was wasted because of the fact that the records were incomplete and no proper follow-up of the surgical procedures which were done was ever possible. It is to be hoped that at least one of the contributions to humanity from this present world conflict may come from a study of the compilation of records upon the numerous peripheral nerve injuries which have occurred This can only be accomplished, however, by coordination of the Army and Navy medical services and those agencies which deal with the veteran after his discharge, to the end that complete follow-up records of the return of sensation and motion following surgical procedures may be obtained by making the veteran's compensation contingent upon his examination by competent neurologists and neurological surgeons at intervals for a sufficient length of time to draw conclusions from his case

The subject of peripheral nerve injuries is an enormous one and a clinic could be devoted to any one of the many aspects of that subject However, there are a few fundamental facts concerning the diagnosis and treatment of peripheral nerve injuries which should be emphasized and which afford a practical working knowledge sufficient to enable the physician to arrive at a correct diagnosis and advise his patient what can and should be done to regain a useful extremity The most commonly injured nerves are those of the upper extremity the radial the median and the ulnar These are also the nerves when injured, which produce the most disabling function to the patient because they involve the use of his hand It is important

* Professor and Chairman Division of Surgery, Northwestern University Medical School Attending Surgeon Passavant Memorial Hospital, Chicago

to make an early diagnosis to secure apposition of divided nerve ends so that regeneration may occur promptly and function return to the hand or the upper extremity before atrophy of muscles and fibrosis of joints have made the effector mechanism so ineffective that it matters little whether nerve regeneration takes place

RADIAL NERVE INJURIES

The characteristic deformity of a radial nerve lesion, which occurs most commonly as the radial nerve winds around the humerus in the upper arm, is that of a dropped wrist and fingers (Fig 1) The hand cannot function properly when the wrist is flexed As Kanavel pointed

Fig 1—Drop-wrist deformity of a radial nerve lesion

out many years ago, the position of function of the hand is that of slight dorsiflexion at the wrist, extension of the proximal phalanges at the metacarpophalangeal joints, and semiflexion of the terminal two phalanges with the thumb adducted toward the palm of the hand One can test the power of the hand by attempting to make a fist with the wrist in flexion As a matter of fact, when a fist is made the hand immediately assumes the position of dorsiflexion

When the radial nerve is injured in the arm, paralysis of the extensors of the wrist, fingers and thumb occurs If the lesion occurs high in the arm there is also a paralysis of the triceps muscle and inability to extend the forearm at the elbow The radial nerve is almost purely motor and has a small sensory component, so that there may

be a loss of sensation only in that area bounded by the first metacarpal of the index finger and the metacarpal of the thumb. This is the area of isolated supply to pinprick sensation. The anatomical supply of the radial nerve has a much larger extent but in the presence of intact median and ulnar nerves the overlap of sensation to pinprick may be so great that the insensitive area is only that small area of skin just described (Fig 2)

When testing the ability of the patient with a radial nerve lesion to extend the fingers, the thumb or the wrist, it is necessary that the palm of the hand be placed flat on the table and the patient then be asked to extend his wrist or fingers. If this position is not assumed it is possible for the patient to flex his fingers strongly, and for the wrist to assume passively a position of dorsiflexion which may be mistaken for a pure extensor movement. Likewise, when testing for

Fig 2—Types of loss of sensation in a radial nerve lesion

extension of the fingers they must be placed flat on the table and then the patient must be asked to extend them

MEDIAN NERVE INJURIES

Certain simple tests for motion and sensation provide a method of making the diagnosis of a median nerve lesion. The paralysis and marked atrophy of the small hand muscles which follow a median nerve lesion produce a striking, characteristic clinical picture. The thenar eminence becomes flattened and the metacarpophalangeal joint of the thumb stands out like a bony knob over which the skin is drawn tightly. The thumb falls back to be in the plane of the palm and as a result the typical "ape hand" is seen (Fig 3). Paralysis of the flexor sublimis and the lateral portion of the flexor profundus digitorum muscles, due to a median nerve lesion in the arm, is evidenced by an absence of flexion of the index finger and feeble flexion

of the middle finger. When the patient attempts to make a fist, the index and middle fingers flex only slightly. Paralysis of the flexor longus pollicis muscle makes it impossible for the patient to flex the distal phalanx of the thumb. Apposition and abduction of the thumb at right angles to the palm are impossible because of paralysis of the thenar muscles. It would seem impossible to mistake a median nerve lesion in the presence of these marked losses of motor function. In old cases, however, supplementary movements may have been acquired by the patient to such a degree that the closest examination leaves one

Fig. 3—Typical deformity in a median nerve lesion. Note the flattening of the thenar eminence and the tendency of the thumb to fall back into the plane of the palm.

in doubt. For example, apposition of the thumb to the little finger may be simulated by the action of the adductor pollicis combined with the inner head of the flexor brevis pollicis and flexion of the terminal phalanges of the little finger. The one movement which cannot be imitated, however, is flexion of the terminal phalanx of the index finger.

Confronted with the task of making a diagnosis of a median nerve lesion, the examiner should ask the patient to make a fist, which he cause of his inability to flex completely the index finger is unable to appose the tip of the thumb to the tip of

the little finger because of his inability to adduct the thumb. Or again the patient may be asked to clasp his hands together and one is then able to see the inability of the patient to flex the index finger on the affected side.

The area of loss of sensation to pinprick in median nerve lesions may vary from the area of complete anatomical distribution of the nerve to the isolated supply of pinprick which occupies the terminal two phalanges of the index and middle fingers but in particular the palmar surface of the terminal phalanx of the index finger. The important thing to remember is that an area of sensory loss to pinprick less than the area of anatomical distribution may not be accepted as evidence of a partial lesion, nor as a sign of recovery of function after operation. The large overlap of the radial nerve to the palm of the hand accounts in a large measure for this variation in the size of the area of sensory loss to pinprick (Fig. 4).

Fig. 4—Types of loss of sensation in median nerve lesions

The skin of the palm in median nerve lesions often is purplish cyanosed, red and cold, and it may be dry, chapped and scaly. Ridging and hypertrophy of the nails occur and in contrast to the normal hand the nails are pinched in at their sides so that the surface becomes more convex. Trophic ulcers occur commonly on the distal phalanx of the index finger as a result of cigarette burns (Fig. 5).

A rather large number of median nerve lesions, and not infrequently sciatic nerve injuries, may be characterized by the predominance of pain. This type of lesion was described first during the American Civil War by S. Weir Mitchell, who characterized its intensity under the name of "causalgia," a term which should be reserved for this clinical entity alone. In such cases total paralysis of the muscles below the level of the wound is rare, but some weakness in movement is always present in the flexors of the index finger and the thenar muscles.

Several cases of causalgia have been observed as a result of injuries

received during the present war and two types of causalgia are now apparent. In the one, the patient receives relief from his pain by immersing the hand in warm water and in the other type relief is obtained by immersing the hand in cold water. Oscillometric studies show that there is a marked vasoconstriction of the vessels of the

Fig 5—Nail changes and ulceration of skin in median nerve lesions

affected part in the first type while in the second group there is a vasodilatation of the vessels. It has been found that in both types of cases interruption of the sympathetic nerve supply to the affected part relieves the pain. The exact mechanism of this relief of pain is now investigation.

ULNAR NERVE INJURIES

Like injuries of the median nerve, ulnar paralysis produces a characteristic deformity of the hand which is very striking (Fig 6). When the lesion of the nerve is above the wrist, these patients are unable to flex the proximal or distal phalanges of the ring and little fingers, to abduct or adduct the fingers when they are extended, to adduct the thumb, to contract the flexor carpi ulnaris, and to abduct or appose the little finger. When the lesion is at the wrist, the flexor carpi ulnaris and flexor muscles of the little and ring fingers are spared. The most

Fig 6—Atrophy of the hypothenar eminence and interosseous spaces with flexion of the little and ring fingers are typical of the deformity produced by ulnar nerve lesions.

striking symptom is the atrophy of the small hand muscles which occurs rapidly and from which recovery is slow and often doubtful. The atrophy in the first dorsal interosseous space is marked and that present in the other interosseous spaces gives the hand a skeleton-like appearance. The "clawed hand" deformity results from the unopposed action of the extensor communis digitorum, which draws the little and ring fingers into extension at the metacarpophalangeal joint, and as a result the distal phalanges become flexed. The hypothenar eminence may become so atrophied that only a thin band of tissue may be palpated.

Just a few simple tests will bring out the great loss of function which follows an ulnar nerve lesion. The patient cannot appose the little finger to the thumb, nor can he form a cone with the fingers and thumb (Fig 7). When the fist is closed the ring and little fingers may be imperfectly flexed. The patient is unable to grasp any object, such as a folded newspaper, between his thumb and index finger. When he is asked to do so and to hold it tightly, he flexes the second phalanx of the thumb vigorously and presses the tip awkwardly against the outer margin of the first phalanx of the index finger.

Fig 7—Inability of patient with an ulnar nerve lesion to form a cone with the fingers

(Fig 8) The patient cannot abduct and adduct the fingers with the palm of the hand flat on the table nor can he scratch the top of the table with the tip of the little finger. Just as is the case in radial and median nerve paralyses, the patient with an ulnar palsy may develop supplementary muscle movements which lead to confusion in determining the exact extent of the motor loss. For example, the extensor pollicis longus muscle is the prime mover in abduction of the thumb, and in ulnar nerve lesions it may wholly supplant the loss of the abductor muscle of the thumb. Even abduction of the fingers away from the midline may be accomplished by forcibly extending the first phalanx, particularly of the index and little fingers.

Here again examination for loss of sensation alone may make it possible to determine an ulnar nerve lesion. The most extensive loss of sensation in an ulnar nerve paralysis occupies the ulnar border of the palm, the palmar and dorsal surfaces of the little and the ulnar

Fig 8—Inability of patient with an ulnar nerve lesion to grasp a newspaper between the thumb and index finger without vigorously flexing the second phalanx of the thumb.

half of the ring fingers (Fig 9). This is the anatomical distribution of the nerve. However, the isolated area of loss to pinprick sensation may occupy only the palmar and dorsal surfaces of the little finger and a small triangular area on the dorsal surface of the hand over the fifth metacarpal bone. It cannot be emphasized too often that the

Fig 9—Types of sensory loss in ulnar nerve lesions.

rest of the area of anatomical distribution may be sensitive to pinprick because of overlap from the uninjured median and radial nerves.

As is true in median nerve lesions, trophic and vasomotor changes are well marked in ulnar nerve lesions. The little finger is usually cold dry, and a purplish discoloration is present. The little fingernail is ridged hypertrophied and deformed. It is not uncommon to find an ulceration on the tip of the little finger usually produced by a burn

COMBINED MEDIAN-ULNAR NERVE INJURIES

In war injuries the median and ulnar nerves are frequently injured in the same patient. The deformity which follows a complete lesion of these nerves resembles an "ape" hand even more closely than does a median nerve paralysis alone. The wrist is slightly hyperextended, and the hand inclines toward the radial side. The thumb is abducted and lies in the plane of the palm of the hand while the first phalanges are extended moderately and slight passive flexion of the last two phalanges is present. Muscular atrophy is marked in the hypothenar and thenar eminences and in the dorsal interosseous spaces (Fig. 10).

Fig. 10—Note the marked atrophy of the thenar and hypothenar eminences in a patient with combined median-ulnar nerve lesion

Sensation to light touch is lost over the palmar and dorsal surfaces of all the fingers, excepting the areas supplied by the radial nerve at the ulnar border of the dorsum of the hand. The loss of sensation to pinprick varies considerably according to the degree of overlap of function from the uninjured radial and musculocutaneous nerves (Fig. 11).

Vasomotor, secretory and trophic changes in these combined injuries are similar to those found in cases of paralysis of the ulnar and median nerves alone. However, in one patient who had been shot in the arm there was an injury to the brachial artery and the skin was

cold, cyanotic, glossy and edematous while the nails were hypertrophied and deeply ridged

Fig. 11—Sensory loss in a combined median-ulnar nerve lesion

BRACHIAL PLEXUS INJURIES

When making a diagnosis of brachial plexus injuries, many of which have occurred as a result of gunshot injuries during the present war it is a common habit to attempt to group them into the classic upper brachial plexus injury described by Erb or the lower type of injury to which Klumpke's name is given. This is not difficult to do in those patients who suffer from a brachial plexus injury at birth but the levels of the lesion in individuals injured in automobile accidents, by stab or by gunshot wounds are not so easily classified. When the major paralyses produced are in the hand they resemble the paralysis described by Klumpke. In other words, the muscles paralyzed are those supplied by the ulnar and inner head of the median nerve.

It is much more helpful to the patient and to the physician if the function of each muscle in the upper extremity is examined and designated as weak or paralyzed on a chart with diagrams of the brachial plexus and the muscles supplied by each of its divisions. If this is done a classification into types not only becomes unnecessary, but its futility is fully recognized and instead the component parts of the brachial plexus are singled out for attention. Injuries of the brachial plexus as the result of stretching due to depression of the shoulder and rotation of the head and chin to the opposite side or to

direct blows to the supraclavicular area may recover spontaneously over a period of several months

SCIATIC NERVE INJURIES

An injury of the sciatic nerve may not be classed as such if its peroneal or tibial division is injured alone in the thigh, as is frequently the case in a bullet or a shrapnel wound. When the entire sciatic trunk is injured, the deformity is unmistakable, the foot dangles and drops as the patient walks and it is brought down in a flail-like manner. All of the muscles below the knee are paralyzed, and the patient is un-

Fig. 12—Sensory loss in a lesion of the sciatic nerve

able to stand on his heels or toes. The knee jerk is always present and the Achilles jerk is always absent but muscle atrophy may be masked by the edema and infiltration of the tissues of the leg. Sensation is diminished or lost over the entire foot with the exception of the inner border of the arch and the internal malleolus and the outer side of the leg to the knee. The overlap of the adjacent uninjured nerves is considerable so that the upper level of the loss of pinprick may extend only to the middle third of the leg. As was noted in the median nerve, causalgia of the sciatic nerve occurs commonly. The pain is referred to the sole and may be associated with a spasm of the

muscles of the sole of the foot. Ulcerations of the plantar surface of the foot are common, and hyperkeratosis frequently occurs so that the skin over the dorsum of the foot may be covered by scales and crust (Fig. 12)

PERONEAL NERVE INJURIES

The deformity produced by a peroneal nerve injury is similar to that produced in a radial nerve lesion. The footdrop which occurs is complete and is often accompanied by a slight drop of the first phalanx of all of the toes. The steppage gait is characteristic and the

Fig. 13—Sensory loss in a peroneal nerve lesion

point of the foot is dropped and abducted. It is necessary to immobilize the knee of the patient when one examines for voluntary movement, but it is not difficult to observe that dorsiflexion of the foot and toes is impossible. Adduction of the foot may be performed by the tibialis posterior muscle, and the distal phalanges of the toes may be extended by contraction of the interosseous tendon, but abduction of the foot is impossible. It is important to remember that strong flexion of the toes may occasionally result in inversion and slight dorsiflexion of the foot by a mechanism similar to that which

produces extension of the hand in radial nerve lesions when the flexors of the fingers are strongly contracted

Sensation is lost over the dorsal surface of the foot, the anterior and lateral surfaces of the leg. In the foot sensation is lost to the base of the toes, extending outward to a point between the fourth and fifth toes and inward to the base of the first metatarsal bone. Just as in radial nerve lesions, the isolated supply to pinprick sensation may be extremely small and is usually represented by a narrow band which extends from a point a little above the junction of the lower and middle third of the outer surface of the leg, diagonally across the dorsum of the foot to a point over the middle of the metatarsal bone of the great toes (Fig 13)

TIBIAL NERVE INJURIES

Lesions of the tibial nerve below the popliteal space are not common, and isolated lesions of the tibial division of the sciatic above that point are extremely rare. There is paralysis of plantar flexion of the

Fig 14—Sensory loss in a tibial nerve lesion

foot and true adduction of the foot is impossible. If it can be performed, it is always accompanied by elevation of the foot and then is produced by contraction of the *tibialis anterior* muscle. Flexion and separation of the toes are abolished, but the foot may be plantar flexed feebly by the *peroneus longus* muscle. Walking is difficult and the foot hangs down, is swollen, edematous and discolored.

Sensation is lost over the sole of the foot except at the inner border (Fig 14) and frequently causalgia may occur, particularly in incomplete lesions of the tibial nerve. Trophic ulcers of the malleoli, heel

and toes, nail changes and edema are common, and in one of our own cases an indolent ulcer of the heel was the most disturbing symptom which kept the patient from work.

OTHER NERVE INJURIES

The most commonly injured peripheral nerves have been mentioned, but of the remaining nerves the axillary, musculocutaneous and femoral are occasionally injured. The *axillary nerve* may be injured as the result of fracture of the head of the humerus and subglenoid dislocations. Paralysis of the deltoid muscle with loss of abduction of the arm from the side is the most characteristic symptom. Injuries of the *musculocutaneous nerve*, which innervates the biceps muscle, are rarely seen in civil life. Recently in the European Theater of Operations the opportunity was presented of observing three patients with isolated musculocutaneous injuries and the resulting paralysis of the biceps muscle. All of these injuries occurred in paratroopers and were produced by slipping of the parachute bands off the shoulder and across the upper arm so that the nerve was injured by direct pressure. The *femoral nerve* may become involved by tumors, operative wounds, psoas abscess or in the prolonged gynecologic operations in which the thighs are strongly abducted. If all the branches of the nerves are involved, the hip joint cannot be flexed and the leg cannot be extended.

ELECTRODIAGNOSIS

The muscles paralyzed as a result of a peripheral nerve injury react abnormally to electrical stimulation. They do not react to the faradic current and although early after injury they are hyperexcitable to the galvanic current this reaction disappears after two weeks. Then the quick reaction of the normal muscle is replaced by a slow contraction of the muscle sarcoplasm which is the only contractile tissue remaining. This is a very simple statement of the "reaction of degeneration," but it is a practical means of using a rather confusing law.

Recently, experimental work by Pollock and his associates has produced very interesting results in new methods of electrodiagnosis. By the use of currents of varying duration and strength it would appear that it will be practical to determine whether or not regeneration is occurring in a repaired peripheral nerve or whether degeneration is complete and surgical repair is indicated. The practical importance of such an electrodiagnostic method can hardly be overstated because it affords a method of determining whether regeneration of nerve fibers is occurring before any clinical evidence of return of muscle function can be detected.

DIFFERENTIAL DIAGNOSIS

The greatest sin which can be committed is to ignore the possibilities of a peripheral nerve lesion at an early stage when repair of that nerve would mean the difference between a completely successful functional result and a failure when undertaken at a later date. The differentiation of peripheral nerve lesions from *severed tendons*, *ischemic paralysis*, or *fibrotic and inflammatory reactions* is not difficult. The combination of motor and sensory loss and the change in the reactions to electrical stimulation readily differentiates these lesions. The segmental distribution of the paralysis and dissociation of sensory loss aid in the differentiation of intramedullary spinal cord lesions, such as syringomyelia and tumors. It must be remembered that a peripheral nerve injury is a lesion of the lower motor neuron and always produces a loss of motion coupled with a loss of sensation whereas, for example, anterior poliomyelitis produces only a loss of motion.

The disturbances of motion and sensation which are found in *hysteria* never conform to the known organic symptoms which accompany specific peripheral nerve lesions. For example, a patient who received a trifling injury to the arm while at work maintained that he was unable to flex the wrist or any of his fingers. Yet, when he was asked to do so, he could appose his thumb and little finger and could grasp a piece of paper tightly between the thumb and index finger. The first movement was a test for median nerve function and the latter a test of function of the ulnar nerve. The loss of sensation in a functional lesion is likely to be glove type or may resemble some geometric figure.

As a result of injuries received during this war it may not be uncommon to encounter contractures and loss of function of the hand which occur when the site of the wound may be at a point on the body far removed from the hand. In such instances the hands will appear cold and cyanotic, the amplitude of the pulse may be diminished, perspiration may be excessive and the skin may appear macerated. This clinical entity has been designated as a *reflex nervous disturbance* and later as a *physiopathic affection*, by others it has been called "congealed hand." Carefully directed and persistent physical and psychotherapeutic treatment will result in a cure of these patients.

Severe cases have been observed as a result of gunshot injuries received in the upper extremity in the present war which have involved the *major arteries* of the extremity without direct injury to the nerve. The loss of function which has resulted, however, has been one which is difficult to differentiate clinically from an injury to the peripheral

nerve and is undoubtedly the result of a loss of function of the nerve trunk due to interruption of its blood supply. The rapid onset of muscle atrophy in these cases with the accompanying vasomotor disturbances of the skin have made the prognosis very serious.

SURGICAL TREATMENT

Differentiation of Anatomical and Physiological Lesions—Having determined that a peripheral nerve lesion exists the next problem concerns its treatment. There is one important fact which must always be kept in mind and this is that there is no way by which complete anatomical and physiological interruption of a nerve trunk can be differentiated. It can be decided whether or not the loss of function is complete or incomplete and if it is incomplete anatomical division cannot be present except as a lateral notch. In the presence of a complete physiological interruption, one may say that an anatomical lesion does not exist only when subsequent examination shows some evidence of return of function. Complete paralysis of all the muscles supplied by a peripheral nerve below the level of the lesion, loss of normal electrical reactions of the muscles, extensive and rapid muscle atrophy, and loss of sensation in the area of isolated supply of the nerve may be accepted as evidence of complete interruption of nerve function.

We have had the opportunity of seeing many cases which clinically were complete interruptions of a peripheral nerve the result of injury by small pieces of fragmenting Oerlikon shells, with wounds of entrance in the skin which made it seem very definite that there was an anatomical lesion of the peripheral nerve. These nerves were explored surgically only to find that the nerve trunk had not been injured anatomically but that it had been concussed by the high velocity fragment. Obviously, these injuries would recover without operation but there is no way of determining clinically the difference between an anatomical and a physiological lesion of the nerve trunk when the symptoms are those of a complete lesion. In such instances the patient deserves and must have the advantage of a surgical exploration.

Primary Suture—There is one rule which should be followed religiously in the presence of a peripheral nerve lesion which requires surgery and that is that *the nerve should be repaired as early as possible*. Only in this way can one look forward with confidence to the successful return of motor and sensory function. There are, of course many factors which influence the time at which a nerve may be repaired but this is the ideal situation for which one must strive.

It has been our practice to suture a divided peripheral nerve immediately after careful surgical débridement of a wound has been carried out if the interval is not longer than six hours after receipt of the injury. We believe that any wound of the soft tissues surgically treated within six hours after its receipt can be cleansed with soap and water, necrotic and torn tissue carefully removed, the wound closed, and primary healing obtained. As the result of our experimental investigations, we believe that it is possible to close wounds primarily after careful surgical cleansing when they are received later than six hours after injury and up to twelve hours, provided that any one of the *sulfonamide powders* is introduced into the wound. It has also been found that the injection of sulfathiazole jelly into the depths of a penetrating wound immediately will prevent a development of infection when surgical cleansing and débridement are carried out as late as eighteen hours after the wound has been received and when sulfonamide powder is introduced into the wound at the time of receipt and nerve repair. From experience with the wounds of the extremities involving the nerves received by British and American soldiers during the African campaign, it was found that infected wounds which had eventually healed could be reopened and the nerve repaired at a much earlier time than has been our practice in the past. This is true because sulfonamide powders were introduced into the wound at the time of the secondary operation. It is not necessary, therefore, to wait for many months before repairing a peripheral nerve to avoid the danger of lighting up a dormant infection.

Studies of experimental gunshot wounds without the introduction of the sulfonamides and the study of the use of sulfonamides in nerve wounds made under surgical conditions have proved quite conclusively that when the sulfonamides are used in reasonable dosages in the wound they have no effect upon the regeneration and healing of the nerve fibers and of the suture line.

If there is an extensive *fracture* of the bones of the extremity accompanying the soft tissue injury it may be impossible to bring the ends of the peripheral nerve together in a satisfactory manner without delaying the operation and endangering the patient's life. In such instances the nerve ends should be secured to the tissue or, if possible, brought together so that they will not retract. The nerve ends should then be sutured together at the earliest possible date following healing of the fracture and the wound. It may be necessary in many of the cases in which there is a large destruction of tissue to cover the large defect in the soft tissue with skin grafts. Many of these cases were observed in those soldiers, both British and American, injured in the

African campaign After these skin grafts have healed, the injury of the peripheral nerve should be exposed and the repair performed

Every method at the command of the surgeon should be used to obtain an *end-to-end apposition* of a divided nerve and this should be done at the earliest possible moment There is no excuse for purposely delaying the suture of a peripheral nerve Every moment of delay is accompanied by muscle atrophy, fibrosis, and ankylosis of joints so that the effector mechanism becomes more and more difficult to rehabilitate Obviously, it will be impossible to obtain an end-to-end suture in many of the gunshot injuries of peripheral nerves which have been received in this war, so that other methods of repairing these large defects in the continuity of peripheral nerve trunks must be employed

Nerve Grafts—Unfortunately, the clinical results of the use of *nerve grafts* employed to repair peripheral nerve injuries received during World War I were on the whole disappointing On the other hand, exact information upon the functional results of these grafts has never been available from a study of the casualties of the American army The experimental work which was performed by Huber and his associates during the last war indicated that certain types of peripheral nerve grafts might well be successful in human beings since they were successful in experimental animals However, this large amount of clinical material was never studied completely nor was it ever possible to make follow-up studies of the patients so that for all practical purposes the contributions of this large amount of material to the progress of peripheral nerve surgery were lost.

Our experiments in animals have shown that autogenous nerve grafts, in which the graft is, as nearly as possible, the same size as the divided nerve, can be successfully performed with return of function Homogenous fresh grafts are the next best method of repairing a large loss in nerve continuity Grafts stored in alcohol or any other fixative substance are doomed to failure and no clinical evidence has ever been adduced to point to a contrary conclusion There may be some hope in the use of nerve grafts stored in saline solution or kept frozen However, under any condition the use of a fresh autogenous graft is much preferred If, for example, the median and ulnar nerves are injured with a loss of continuity which cannot be bridged by the usual method of changing the position of adjacent joints, it is preferable to sacrifice a portion of the patient's ulnar nerve and use it as an autogenous graft to repair the median nerve in order to obtain function of the index finger and the middle finger so that the patient may regain a useful hand Likewise, it would be justifiable to sacrifice

a portion of the tibial nerve to repair the peroneal nerve or the sciatic nerve, and the sacrifice of the cutaneous nerves of an extremity, particularly the larger cutaneous nerves, is wholly justifiable. The use of several segments of a small nerve to repair a defect in a larger nerve in a so-called "cable graft" would appear wholly illogical, difficult and impracticable. As far as clinical results have been reported this has proven to be true, notwithstanding experiments upon animals to the contrary.

The use of a fresh homogenous nerve graft obtained from an amputated extremity offers many more chances for success than does the use of fixed grafts. Our own experience with a portion of a sciatic nerve from an amputated extremity as a graft for an injured tibial nerve provides clinical support for the experimental evidence we have collected. There should be many opportunities at Army and Navy hospitals for confirmation of this work provided careful clinical studies are begun and are carried out over a critical period of time.

Experimentally it has been shown that the *vascularization* of the graft is most important in its function as a bridge between the divided nerve ends. Fixed graft material or dead graft material cannot be vascularized and, in our opinion, fails because of that reason. We have found that trophic ulcers do not develop when nerve ends are brought in apposition either directly or by means of either an autogenous or homogenous graft. We also believe that perhaps the most important reason for the failure of the return of function after repair of a peripheral nerve injury by the use of a graft is the fact that by the time the nerve fibers regenerate through the graft and reach the distal suture line there has been a growth of scar tissue which blocks the downgrowth of the nerve fibers into the distal segment of the nerve. It is true that this point cannot be proved conclusively in animals because of the inability to use a graft of sufficient length to be comparable to that which would be used in a human being and because nerve fibers grow much more rapidly in animals than they do in man. However, our clinical experience in two cases has shown us without any question that resection of the distal suture line (that is, the line of union between the distal end of the graft and the distal segment of the nerve), after a time sufficient for the nerve fibers to have grown down through the graft, facilitates the downgrowth of the nerve fibers into the distal segment of the nerve and the return of function.

Time Interval between Injury and Repair as Factor in Subsequent Return of Function—As far as the ability of the nerve fibers to regenerate is concerned, there is no time interval between the time of the injury

and the time of repair beyond which an end-to-end suture will not be successful. The time interval is dependent entirely upon the effector mechanism. It is the development of muscle atrophy, of fibrosis and ankylosis of joints, which determines whether or not there can be a successful return of function after a peripheral nerve suture. Therefore, it is important to keep the muscles and joints of the extremity as mobile and in as good tone as is possible by physical therapy methods. Passive movements of the joints, massage, and proper splinting of the dependent parts of the paralyzed extremity are extremely important. They are also important after the peripheral nerve has been sutured and during the period of regeneration.

Suture Materials—There has been a great deal of discussion about the method by which peripheral nerves should be sutured. It can be said simply and directly that the nerve ends should be apposed by the finest suture material obtainable which will give the smallest amount of tissue reaction. We have at various times in our experimental work used human hair, tantalum wire and other suture materials, but we have found that unbraided strands of the finest black, twisted silk answers the requirements most accurately. The suture must never be placed through the body of the nerve but should only bring together the epineural sheaths.

Criteria of Regeneration after Repair—Finally, the same care in the examination of motor and sensory function as is used in diagnosis must be observed in attempts to determine recovery. When there is return of pinprick sensation in the isolated area of sensory supply of the nerve, regeneration of the repaired nerve ends may be said to have occurred, but only then. Likewise when there has been a return of muscle movement innervated solely by the involved nerve, regeneration may be judged to have occurred. Failure to adhere to these strict requirements has made many reports in the literature of recovery of function after nerve repair practically valueless.

THE ORGANIC ORIGIN OF APPARENT FUNCTIONAL NERVOUS DISEASE

LEROY H SLOAN, M D *

CASE I

Our first patient, a white male aged 45 years, was first seen in January complaining of weakness, easy perspiration, loss of a slight amount of weight, *ready flushing*, hot flashes, restlessness and tremor of the hands together with palpitation of the heart. This symptom complex was not constant but came in attacks or *waves*. During such waves the patient was compelled to sit down. After resting for a few minutes the symptoms and signs would disappear and the patient would return to his duties. On some days the spells were frequent while on others they came only occasionally. There was loss of weight, loss of appetite, increasing *frequency of bowel movement*, moderate vertigo and insomnia.

The patient had always lived with his mother. He had never married. He had never been able to mix well with people and as a result had isolated himself from practically all social contacts and given himself over to the care of his mother. The mother died during the preceding April. Some three or four months afterward the above train of symptoms put in their appearance.

Several clinical syndromes come to mind. Does the patient have hyperthyroidism? While the symptoms suggest such a diagnosis, the wavelike character of the cycle does not. Also, the basal metabolic rates which were taken many times were extremely labile—one day up and the next down, inconsistent and not dependable. The pulse during the attacks would be rapid and at rest, afterward, would be normal. It was our impression that the patient did not have either a toxic adenoma or hyperplastic thyroid to account for his difficulties. There was no palpable enlargement of the thyroid at any examination.

A second clinical syndrome for passing consideration is the currently popular male climacteric. This patient had to all ordinary study no evidence of a male menopausal status. True, he had never experienced any real sexual urge but his present gonadal status varied little from that of his past years.

From the Illinois Central Hospital, Chicago

* Professor of Medicine, University of Illinois School of Medicine, Director of the Medical Service, Illinois Central Hospital, Adjunct Staff, St. Luke's Hospital

A third syndrome suggested by the easy palpitation, flushing, rapid alteration in pulse rate, variation in blood pressure, and weakness, was postural hypotension. But here again there was no finding to clinch such a thought. The pressure, while very labile, did not conform to the pattern of postural drop.

The syndrome of hyperirritable carotid sinus could not be confirmed.

During the period of the last war this case would undoubtedly have been labeled as neurocardiac asthenia or effort syndrome. Blushing, flushing, sweating, palpitation, nervousness, tremor, irritability, apprehension and loss of confidence with labile blood pressure and more labile pulse—what more could be needed?

During his first sojourn in the hospital there was relatively little change in his status. He continued to be a very apprehensive, easily irritated, anxious type constantly interrogating all who came near him and at all times asking questions about his physical and laboratory findings, his future status in his work, and in society in general. Several capable internists saw him from time to time and all came to the same conclusion—that this patient aside from a mess of infected teeth was suffering from a functional condition conforming more to an anxiety neurosis than to any other syndrome or classification. This impression was confirmed by psychiatric consultation. So our patient was discharged from the hospital with the advice to have his teeth cared for, to keep with other people, to obtain and consume a generally nutritious and balanced diet, to engage in the usual and currently considered normal functions of existence, and to report from time to time for further study and check up.

The patient returned in November almost eleven months after his initial admission to the hospital. About six months after his previous discharge he first began to have pain in the left arm. He had gained a little weight prior to this time, had received attention to his teeth with the extraction of most, had thought that he was fairly well. His failure to gain much weight he attributed to his inability to procure sufficient food because he still lived alone, still ate wherever he happened to be. His friends had been very cooperative and his employers more than kind. A much easier job had been assigned to him. On examination in November the patient showed all of the symptoms and signs mentioned above—the waves of flushing, of sweating, of palpitation, and so forth—but—there was beginning *atrophy* of the small muscles of the hand, there was numbness of the small and ring fingers and the *complaint of pain* which began in the arm, advanced to the left shoulder and subscapular area and into the cubital space.

In the supraclavicular area on the left there was a small gland. This gland was removed and microscopic examination showed it to be metastatic adenocarcinoma. Here then was the organic origin of our patient's difficulties. Away went the anxiety neurosis, away the cardiac asthenia, away the male climacteric.

The blood pressure remained the same, the heart rate the same, the weight decreased, atrophy advanced, pain became much more severe, more glands appeared. The blood Wassermann and Kahn tests were, as one might expect, entirely negative and the spinal fluid showed no block. It was clear, with only six cells and 29 mg. of total protein, a negative Wassermann reaction and a flat gold chloride curve. When the carcinomatous gland was found, repeat x-rays of the lung and chest cage were made. In the apex of the left upper lobe was an increased soft tissue density. A classical Horner's syndrome made its appearance on the left with enophthalmos, miosis, ptosis. Gradually the pain spread to the right side. Roentgen therapy was given to the area of the left supraclavicular fossa, cervical vertebrae, and the lung. There was a consistently downward course and the patient expired *sixteen months* after his initial complaints. Autopsy showed an adenocarcinoma involving the apex of the left lung, the left cervical and supraclavicular soft tissues, the cervical fifth, sixth and seventh and the first dorsal vertebrae.

CASE II

Our second patient was a clerical worker 57 years of age who had been under treatment in the outpatient department at irregular intervals. The history obtained therein was chiefly of pain in the right shoulder and right arm. This pain had come on following a night of bowling after which he went out into zero weather before he had had an opportunity to cool off. The next morning he developed sharp pain beneath the right shoulder blade. The pain was quite constant and not affected by any motion of the shoulder, the elbow, the wrist or the neck. The pain was worse in cold weather, much worse in very cold weather, relieved in part by heat, either moist or dry, very slightly relieved by salicylates and similar antineuralgic medication. The patient insisted that the pain was now limited to a small area of the arm and elbow region, appeared to originate above the clavicle but was most marked at or near the elbow. From February on the difficulty persisted until he became extremely nervous and took to heavy drinking to relieve the distress. All laboratory examinations were negative except for a slight clouding of the right apex of the

lung which was interpreted after much discussion as probably tuberculosis of minimal extent.

The patient became increasingly difficult to manage, increased the length of his alcoholic sprees, refused hospitalization, became more and more apprehensive but, apart from the slight clouding of the right apex, showed no single pathological or clinical finding of any moment. He was therefore regarded as a high grade psychoneurotic patient with an anxiety state. The alcoholic factor was given due consideration and felt to be just one more added factor in the clinical picture and perhaps the important one. However, he was given a few injections of sodium salicylate and iodide of sodium intravenously.

Radiant heat was advised and administered to him at irregular intervals along with medication by mouth and the usual topical applications for nonspecific neuralgic pain. However, in the minds of all who contacted him there was the settled feeling that here was a high grade psychoneurotic patient trading on a functional difficulty and bathing his depressed spirits in alcoholic libations far and beyond the therapeutic dosage.

In October he finally came into the hospital. Ten days before this admission he had developed pain across the right chest from the midline and referred up to the arm and the muscles of the neck. General examination at this time was again negative. The laboratory examinations were normal throughout. There was no pain of any sort on any motion of the shoulder, elbow, wrist, neck or body. Yet the patient complained bitterly of pain down the right arm and especially along the medial border of the triceps and ulnar border of the lower arm.

Of great importance to all of us should be the continued complaint of the patient of pain in one general area, in this instance in the right arm, shoulder and neck. This insistence points to an organic lesion and not to a functional one. In the functional patient other areas are sooner or later incriminated. Rarely does he stick to one portion of his anatomy. The paucity of physical findings may be present in both. Why did we regard the patient as a psychoneurotic? Chiefly I expect because we could find no other explanation for his distress. Here was a patient who had been divorced, who had a background of unhappiness as the soil for his anxiety state, who had taken to alcohol to cure his difficulties and who continued to *bowl right along* even up to the time when he came into the hospital. His stubborn and uncooperative nature just added that much more evidence that our patient was suffering from a functional state.

But, let us follow him a bit longer. Within a few days after admis-

sion to the hospital the lesion in the apex of the right lung had spread until there was now an area of opacity very suggestive not of tuberculosis, not of an apical cap, but of malignancy. Here, then, was the organic basis for his supposedly functional state. Shortly after this the patient began to show atrophy of the muscles of the lower right arm and hand, the right pupil became smaller than the left, the palpebral fissure narrowed and the bulb retracted—all indicating a Horner's syndrome produced by compression or infiltration of the tissues of the sympathetic system.

This patient began to have symptoms after bowling for several hours and then going out into the bitter cold—a perfect setting for a refrigeration neuralgia or neuritis or whatever one might wish to call it. But, the lesion in the right apex spread, involved the cervical vertebrae, compressed the brachial plexus, comprised the esophagus and the trachea, finally led to a paralysis of peripheral type of the entire right arm with glossy skin, atrophy and weakness.

The patient terminated his earthly sojourn *eighteen months* after his initial complaint. For exactly a year from the time of his first complaint there were no demonstrable bony changes even of minor degree. Now what was found at autopsy on this patient? A carcinoma of the apex of the right lung beginning in the bronchial structures and extending into the superior sulcus area, invading the ribs, the cervical vertebrae, and the soft structures at the base of the neck on the right side.

In my experience the tumors of the apex of the lung have been more often on the right side, have produced pain at some stage in their course, and have originated in the great majority of instances in the bronchial tissues and not in the tissues of the nervous system. In other words, superior sulcus tumors are usually bronchogenic carcinomas.

SUMMARY

We have presented as examples two patients both regarded as suffering from functional nervous disease over a period of weeks and months. Both were shown on further examination to have tumors of the lung, one in the right apex and the other in the left apex. Both were examined by competent internists and neurologists. The one exhibited many of the symptoms and signs seen in panic reactions of anxiety neurosis, the other, consistent pain in the right arm. One lived *sixteen months* and the other *eighteen months* after the initial complaints began. Both were shown at autopsy to have sufficient organic, neoplastic disease to explain all of the symptoms presented throughout the long course of their illnesses.

The consistent segmental distribution of pain is assumed to be of organic origin until proved by long observation not so to be. Pain in the upper chest or arm associated with slight percussion dullness over the apex and linked with a history of even slight hemoptysis is highly suggestive of apical carcinoma. Persisting pain in the arm with atrophy or weakness or numbness of the extremity calls for x-ray study of the apical portions of the lung. A palpable gland in the supra-clavicular area should be removed for microscopic study.

Most of the apical tumors giving the above symptoms and signs have been shown at autopsy to be bronchogenic carcinomas. Occasionally, as in one seen previous to the case described and showing much the same clinical picture, they are from nervous tissue of the sympathetic system.

BENIGN LYMPHOCYTIC CHORIOMENINGITIS

LOREN WILLIAM AVERY, M D *

PRESENTATION OF CASES

As a basis for discussion of lymphocytic choriomeningitis the following clinical cases are presented

CASE I—F B, a white male of 17 years, was admitted to Presbyterian Hospital, Chicago, in March, 1935. He had been well up to fourteen days prior to admission. At that time, both he and his younger brother suffered from a mild upper respiratory disorder characterized by slight elevation of the temperature, headache, nasal discharge and general malaise. These symptoms lasted for about a week after which time both patients appeared to have recovered. In a few days, however, the older brother became ill complaining of throbbing headache, photophobia and stiffness of the neck. He again had a slight elevation of temperature and a purulent nasal discharge. He was not severely ill and was able to travel a distance of fifteen miles to consult his physician for local treatment of the nasal condition. Four days before admission to the hospital the above symptoms increased in severity and vomiting was present.

Upon examination the patient was alert, lying quietly in bed shading his eyes from the light. He was able to give an accurate and complete description of the details of his illness. The neck was rigid and painful to pressure. The Kernig sign was bilaterally present. The deep and superficial reflexes were present and equal on the two sides. The plantar reflexes were of the flexor type. There was no disturbance of sensation or coordination.

The temperature was 100.8° F. The pulse ranged from 66 to 88. The leukocyte count was 15,000, being predominantly polymorphonuclear in character. There were 4.6 million red blood cells. The hemoglobin was 90 per cent. The urine was negative.

The spinal fluid was clear. The pressure was 105 mm. It contained 440 cells per cubic millimeter, 44 per cent of which were mononuclear lymphocytes, 56 per cent were polymorphonuclears. The Nonne and Ross-Jones reactions were positive. The total protein was 36 mg per 100 cc. The gold curve was 1111221100. The sugar was 54 mg per 100 cc. The Wassermann reaction was negative. The spinal

From the Neurological Department, Presbyterian Hospital, Chicago

* Associate Professor of Neurology (Rush), University of Illinois College of Medicine, Associate Attending Neurologist, Presbyterian Hospital

fluid was found to be sterile on culture and no organisms were found on direct smear

The patient improved quickly following the initial spinal puncture. The temperature returned to normal. The spinal fluid twenty-four hours after admission contained 280 cells of which 50 per cent were mononuclear lymphocytes. Four days after admission 90 cells were found in the spinal fluid. These were all lymphocytes. The patient was dismissed twelve days after the onset, being entirely free from all symptoms.

CASE II—G H, a white boy of 8 years, fourteen days before observation suffered a typical attack of measles without any complications. Two days before he was seen his mother noticed that he was apparently ill. He had a temperature of 100.2° F, complained of headache, soreness and stiffness of the neck, and refused to eat. Vomiting occurred.

Upon examination in his home, it was found that the lad was not severely ill. He was in bed and was playing with his toys. The neck was distinctly rigid. The Kernig sign was slightly positive. The temperature was 99.8° F. There were no evidences of cranial nerve involvement, and motor power, sensation and coordination were found to be normal. The reflexes and optic fundi were normal.

The spinal puncture was performed at the home. The fluid was clear, and the pressure was 180 mm. Ninety cells were present, all of which were lymphocytes. The Nonne and Ross-Jones reactions were positive. The colloidal gold test gave a suggestive meningeal curve. The Wassermann reaction was negative. The sugar was 60 mg per 100 cc. The fluid was sterile on culture and no organisms were found on direct smear.

The clinical symptoms rapidly disappeared so that within seventy-two hours the boy felt and appeared well.

CASE III—G W, a white male of 54 years, was admitted to Cook County Hospital in April 1932. He was a vagabond. The subjective history indicated that a week before admission he had a slight chill and began to have severe headache and stiffness of the neck as well as general malaise. Two days later he complained of double vision. Nausea and vomiting were present.

Upon examination on admission it was found that the pupils were equal and reacted to light and convergence. There was no evidence of paralysis of the extrinsic ocular muscles and subjectively the diplopia had disappeared. The optic fundi showed slight blurring of the disks but no swelling was present. There was no evidence of paralysis of the skeletal muscles. The reflexes were equal on the two sides and generally brisk. The plantar reflexes were normal. There was no disturbance of sensation or coordination. The neck was rigid, and the

Kernig and Brudzinski signs were positive. The patient appeared ill. The temperature was 102.4° F. Herpes were present on the lips, and the tongue was dry and coated.

The blood showed a polymorphonuclear leukocytosis of 12,000, and there were 3.9 million red cells. The hemoglobin was 70 per cent. The blood Wassermann reaction was negative. The spinal fluid pressure was not taken, but the fluid was clear and colorless. Six hundred and eighty cells were reported in the spinal fluid, 75 per cent of which were mononuclear lymphocytes. The Pandy reaction was moderately positive. The protein was 100 mg per 100 cc. The colloidal gold curve was 0112222100. The sugar content was 67 mg per 100 cc. The Wassermann reaction was negative. On culture the spinal fluid was sterile and no organisms were found on direct smear of the sediment which formed in the fluid.

The patient continued to be rather ill for two weeks. There was an afternoon elevation of temperature from 101° to 102° F. During this time the headache and stiffness of the neck persisted. A gradual improvement began after the fourteenth day but it was not until the sixth week after onset that the symptoms entirely disappeared. Repeated spinal punctures during the time the patient was in the hospital showed varying degrees of pleocytosis of the fluid which had the tendency to decrease gradually as the clinical picture improved. He was discharged nine weeks after admission.

CASE IV—L. S., a white male of 32 years, was admitted to Presbyterian Hospital, Chicago, in May 1936. He had been well up to fourteen days previous to admission. At that time he suffered from a mild upper respiratory disorder characterized by a slight elevation of temperature and slight nasal discharge and frontal headache. Eight days before admission he complained of weakness and soreness of the neck and back. The day before admission he complained of severe frontal headache, slight nausea, stiffness and pain in the neck.

Upon examination it was found that the neck was rigid and painful to motion. The Kernig sign was bilaterally present. The deep and superficial reflexes were present and equal on the two sides.

The temperature was 101° F. The pulse ranged from 72 to 84. The leukocyte count was 12,900 and was predominantly polymorphonuclear in character. There were 4.4 million red blood cells, and the hemoglobin was 84 per cent. The urine was negative.

The spinal fluid pressure was elevated and the fluid was clear. It contained 410 cells per cubic millimeter, all of which were lymphocytes. The Nonne and Ross-Jones reactions were positive. The total protein was 104 mg and the sugar was 45 mg per 100 cc. The gold curve was 0012332300. The Wassermann reaction was negative.

A subsequent spinal puncture two days later showed 390 lymphocytes. The Nonne and Ross-Jones reactions were negative. The total

protein was 87.7 mg. The sugar was 62.7 mg. The gold curve was 1122221100. Bacteriological examinations of both samples of spinal fluid revealed no organisms.

A third spinal puncture done a week after admission revealed 86 lymphocytes.

Recovery was somewhat slow especially in regard to nausea and vomiting. This, however, may have been more referable to a duodenal ulcer than to the meningitis. At the end of two weeks the patient was free from all symptoms of the disorder. He has remained well and no sequelae have been observed.

COMMENT

The above cases all have certain features in common. Their onset was relatively sudden following some mild infectious disorder. They all occurred in the spring. The clinical symptoms in all the cases were those of meningitis. In all, the pleocytosis of the spinal fluid was preponderantly lymphocytic in character though in Case I there was an early preponderance of polymorphonuclears. In all the cases the spinal fluid was sterile, the sugar content was normal and the globulin was slightly increased. Recovery occurred in all the cases.

Diagnosis—It is evident that these clinical syndromes belong to types of meningitis characterized by lymphocytes in the spinal fluid. They must be differentiated from tuberculous meningitis. The mild course of the disorder, the failure to find tubercle bacillus and the normal sugar contents of the spinal fluid definitely indicate that they are not tuberculous meningitis. Syphilitic meningitis, which is also characterized by a lymphocytic pleocytosis, needs a little consideration. The finding of consistent negative Wassermann reactions of the spinal fluid, which at the same time shows evidence of an active inflammatory reaction, is entirely incompatible with a syphilitic infection. Other conditions which produce a lymphocytic pleocytosis such as poliomyelitis and epidemic encephalitis would hardly need to be considered except, perhaps, in Case II in which the pleocytosis was below 100.

These cases all belong to a benign form of meningitis which, in the past, would have been classified as aseptic or serous meningitis. Because of the preponderance of lymphocytes in the spinal fluid they have more recently been classified as *benign lymphocytic meningitis*.

THE BENIGN LYMPHOCYTIC MENINGITIC SYNDROME

During the past decade benign forms of lymphocytic meningitis have attracted considerable interest. While such clinical syndromes have been encountered for many years there had been no unanimity of opinion as to their identity and considerable confusion has always

existed as to their pathogenesis. The earlier conception of these disorders was that they represented the meningeal reaction to acute infectious diseases, acute intoxications or trauma. It has been known for years that in the beginning of many of the acute febrile conditions, especially in childhood, a lymphocytic pleocytosis may be present in the spinal fluid associated with an increase in the volume of spinal fluid with resulting increase in pressure. These syndromes were classified as serous meningitis.

Beginning in 1925 considerable interest was stimulated in reference to this syndrome by the rather frequent reports of sporadic and epidemic instances of a benign type of meningitis. These reports came chiefly from Europe but instances were also reported in America. Wallgren¹ reported an epidemic which he called "meningitis aseptica acuta." From scattered areas in Europe several reports were made and the diseases were designated as "acute benign idiopathic serous meningitis,"² "benign aseptic purulent meningitis"³ and "epidemic meningitis serosa."⁴ In this country the designation was "benign lymphocytic meningitis."⁵

A review of the reported cases indicates that they were all clinically similar. The onset was usually sudden and very frequently associated with some respiratory disorder. The meningitic syndrome was usually rather mild but had the cardinal characteristics of meningitis. These pertinent data were always obtained from the spinal fluid. The fluid was clear and under slightly elevated pressure. There was always an increase in cells ranging from 30 to 1500 or more. This pleocytosis was preponderantly mononuclear lymphocytic in character. However, polymorphonuclear cells were observed, though usually not more than to the extent of 40 per cent. It is interesting that in the early days of the disorder the polymorphonuclear cells were more frequently observed than in the later stages. Instances have been observed in which the identical clinical picture was associated with preponderantly polymorphonuclear pleocytosis during the entire course of the disorder. However, the most characteristic pleocytosis was of the lymphocytic type. The sugar and chloride contents were always normal. The protein content was slightly elevated. No organisms were found in the spinal fluid either by direct smear or culture. The clinical course of the cases was always comparatively mild, lasting from days to months, and recovery always took place. Sequelae were thought to be absent.

Etiology—There was considerable agreement among the various authors that these disorders were due to a filtrable virus. Some suggested that it was an attenuated form of tuberculous meningitis. This

latter concept failed to arouse interest because of the lack of all confirmatory evidence. While most observers believed that it belonged to the virus group of disorders there was a considerable disagreement as to the identity of the virus. Some observers believed it to be related to poliomyelitis while others considered it to be a form of epidemic encephalitis.

These discussions, as to the relationship of this disorder to other virus diseases, were largely terminated in 1935 by the report of Rivers and Scott,⁶ who were able to recover a filtrable virus from the spinal fluid in typical clinical cases. This virus was capable of producing in laboratory animals a constant type of lymphocytic infiltration on the meninges and choroid plexus.

With the recognition of the virus and the study of the resulting pathologic changes as seen in the experimental animal, the term "lymphocytic meningitis" has been replaced by or held to be synonymous with *lymphocytic choriomeningitis*. The virus is designated as the choriomeningitic virus.

Further investigations on the pathogenic role of this virus have revealed several interesting facts. There has been no proven instance in which one patient has contracted the disease from another. This has suggested that there is an animal reservoir for the virus.⁷ In six proven instances of this disorder the virus of choriomeningitis was recovered from gray mice trapped in the homes of five of the patients. Also mice trapped in the homes where infected animals had been known to exist were found to have a high percentage of immunity to the virus. Several cases have also been observed among laboratory workers handling infected mice. Even though other animals are susceptible to the virus, it would appear that one of the sources of transmission is by the way of the mouse.

The cases are seasonally distributed, being most prevalent in the spring. The frequent association of choriomeningitis with respiratory symptoms would indicate that the mode of the infection is through the respiratory tract. The virus is most readily recovered from the spinal fluid or blood taken either at the height of or before the attack. It has, at times, been isolated from the nasal discharges and from the urine. Protecting antibodies can usually be demonstrated in the blood at the end of six to ten weeks and may persist indefinitely.

Clinical Picture—The clinical expression of infection with the choriomeningitic virus is known to be varied. There is a non-nervous type which has many of the characteristics of the "grippe." Clinical evidence of lymphocytic meningitis has been seen in epidemics of gastrointestinal disorders. Besides the classical form of meningeal involve-

ment, cases showing evidence of encephalitis have been seen. Other cases have been described in which the syndrome corresponds to that of meningoencephalomyelitis. Two fatal cases of hemorrhagic encephalitis have been reported by Howard⁹

It is evident that the choriomeningitis virus may produce widespread changes in the body. It seems also to be true that in its nervous manifestations it may produce different clinical and pathologic syndromes. This is in keeping with other types of filtrable virus. The virus of poliomyelitis, at times, produces polioencephalitis and the clinical syndrome in the abortive nonparalytic cases corresponds somewhat to choriomeningitis. The viruses responsible for measles, whooping cough and mumps presumably produce the syndromes of meningitis, encephalitis or meningoencephalomyelitis referable to those diseases.

The usual clinical picture is that of a mild meningitis, having a more or less sudden onset during or following symptoms of a mild upper respiratory disorder. General malaise, headache, fever and stiffness of the neck are always present. Vomiting is frequent but not constant. As a whole, evidences of cranial nerve involvement are insignificant, though blurring of the optic disk is frequently reported.

Spinal Fluid Changes—The changes in the spinal fluid are confined to the cells, the globulin and pressure. The sugar and chloride contents are normal. The gold curve is not significant. The Wassermann reaction is invariably negative and the fluid is sterile. The cells vary greatly in number. However, in the proven cases the cell count was always high. Armstrong⁷ states that a clear spinal fluid with a cell count of over 1200 points to choriomeningitis. The consensus seems to be that the cell count may vary from 30 to 1500 or more.

Course—The course is usually mild, and it may last for only a few days. More severe cases continue for weeks and some for months. Recovery is the rule and, with the exception of the cases reported by Silcott and Neuberger,⁸ no deaths have occurred. Sequelae have not been observed, which differentiates this disease from epidemic lethargic encephalitis.

Pathology—Pathologic reports concerning the changes present in proven cases of lymphocytic choriomeningitis are lacking. There is a report by Howard⁹ containing evidence that the virus may be responsible for cases of hemorrhagic encephalitis.

Silcott and Neuberger⁸ have reported the histopathologic findings from three cases which had the cardinal manifestations of acute lymphocytic choriomeningitis. Their findings would indicate that besides the meningitic changes, moderately severe encephalitis may be present.

in the interbrain. Because these cases were fatal and the cause not proved by virus studies it is not clear that they were due to the virus of choriomeningitis.

CONCLUSION

Some clarification is necessary concerning the concept of lymphocytic choriomeningitis. The term signifies a lymphocytic inflammation of the choroid plexus and meninges. A histopathologic diagnosis is being applied to a clinical syndrome in which meager, if any, valid pathologic observations have been made. This has come about because the virus recovered from the spinal fluid in some cases consistently produces a choriomeningitis in experimental animals. In designating all cases of benign lymphocytic meningitis as lymphocytic choriomeningitis one is assuming that all cases are due to the specific virus. There is evidence that the cardinal clinical manifestations of lymphocytic choriomeningitis can be associated with or follow such disorders as measles, mumps, chickenpox or other virus disorders. The second case reported here was presumably referable to measles. Mackay¹⁰ has observed a lad of 16 years who presented the classical clinical symptoms and spinal fluid findings of lymphocytic choriomeningitis during the course of mumps. More convincing perhaps, is the report of Armstrong¹¹. In a typical instance of lymphocytic choriomeningitis he recovered the virus of herpes simplex from the spinal fluid and was able to fulfill the usual criteria to establish its etiological role.

In the light of our present knowledge it seems premature to regard benign lymphocytic meningitis as always being due to the choriomeningitic virus. While it is probably true that the most frequent cause of benign lymphocytic meningitis is the specific virus, it should be borne in mind that the classical clinical syndrome can be produced by other pathogenic agents.

PATHOLOGIC PYRAMIDAL TRACT SIGNS

Elicitation, Interpretation and Evaluation

VICTOR E. GONDA M.D.*

GENERAL CONSIDERATIONS

In determining why many errors occur in the elicitation and interpretation of some of the important neurologic reflexes, I have come to the conclusion that the textbooks on neurology and neurologic examination do not give an adequate description of this phase of the examination, especially for the beginner. Generally, the information for use in detecting the normal reflexes is satisfactory, but each book describes the techniques somewhat differently and with rather inadequate instructions for eliciting the pathologic signs. The photographs usually are not pertinent and almost invariably show only the end result, omitting a satisfactory illustration of the most important part of the technic.

The interpretation of the elicited reflexes frequently varies, even in the examination of the same patient by different neurologists. This occurs most commonly in patients with a diseased pyramidal tract. Vascular accidents, tumors, syphilis and multiple sclerosis are among the most frequently encountered diseases of the nervous system. The pyramidal pathway is involved in a large number of these cases.

Origin and Course of the Pyramidal Tract—At the present time it is generally accepted that the pyramidal tract has its origin in the precentral convolution (motor area), which coincides structurally with the area of the pyramidal cells, and in the region just in front of it (premotor area). There is a narrow zone (strip region) between these two areas which is of great importance in neurophysiologic research. Circumscribed lesions of any of these areas produce varying manifestations. Because the origins of the different pyramidal pathways lie in juxtaposition in the cortex and after leaving the cortex their anatomic relationship becomes closer, any disease in the pyramidal tract almost always simultaneously involves the whole system. Therefore the resulting signs, at least for general purposes, have to be considered at the present time as characteristic of pyramidal tract lesion.

Many of the fibers originating from the motor cells are very long

Clinical Professor of Neurology, Loyola University School of Medicine
Attending Staff Neurologist, Cook County Hospital, Senior Attending Neurologist, Mercy and Alexian Brothers Hospitals, Chicago

some almost as much as one third of the whole body length. It is little wonder, then, that these fibers are exposed to many pathologic changes. The pyramidal fibers, also called corticospinal, upper motor, central or supranuclear neurons, after decussating at the lower border of the medulla oblongata, end around the anterior horn cells on the opposite side of the spinal cord. Hence injuries above the decussation involve the opposite side of the body, and below the decussation involvement of the pyramidal fibers causes homolateral symptoms. Regardless of the point of injury of the corticospinal neurons, the resulting symptoms are the same.

We do not consider in this discussion those fibers which decussate in the midbrain, pons or medulla oblongata.

Results of Pyramid Tract Lesions—The pyramidal tract is regarded as the chief executive organ in the performance of voluntary movements. A lesion of these pathways causes weakness of volitional movements and not of individual muscles. The resulting paralysis is rarely permanently complete and always affects diffuse muscular groups.

Involvement of the pyramidal system will lead to changes in the regular muscular tone, resulting in hypertonicity in the form of spasticity. It must be remembered that the limbs are flaccid in the early stages of sudden paralysis caused by involvement of the pyramidal system, and in exceptional cases of permanent hemiplegia.

Changes in Reflexes—Disease of the pyramidal fibers also causes some important changes in the reflexes, namely

- 1 *Increase of the deep* (generally called tendon) *reflexes*, e.g., biceps, triceps, radioperiosteal (also called supinator), knee, ankle and jaw jerk. In some cases ankle, patellar and wrist clonus can be elicited as a sign of pyramidal tract disease. However, clonus may also be present in connection with general "reflex irritability," in which case it is less regular in amplitude and rate. There is no standard as to what constitutes a normal deep reflex. The reflex may vary from time to time in healthy individuals, it may sometimes be very brisk but then it is uniform in degree. Differences in one side or the other, or differences in liveliness in the same extremity, e.g., between the knee and the ankle jerks, should make one suspicious of organic involvement of the pyramidal system. It is important to recall that for a time after sudden paralysis due to corticospinal neuron involvement, there is at first a loss of reflexes, supposedly initiated by the so-called shock (cerebral or spinal).

- 2 *The superficial* (also called cutaneous) *reflexes*, e.g., abdominal or cremasteric, are usually *diminished or lost* on the side of the paralysis. There are many ingenious theories to explain this fact, but none

of them has been proved, besides, in many cases the superficial reflexes are not lost at all, and again, in other instances, they are lost only temporarily.

There may be abnormal associated movements which can be observed only when the spasticity is quite marked. Their interpretation is not easy and not always satisfactory.

Atrophy, in the real meaning of the word, does not develop in the involved muscles. There may be some atrophy from nonuse, and after a duration of years there may be slight diminution of response to electric stimuli but never leading to the reaction of degeneration.

THE BABINSKI SIGN

It is apparent that so far we have not encountered a sign which could be used alone as an absolute indicator of organic involvement of the pyramidal tract. There was no known single objective sign definitely proving the involvement of the corticospinal fibers until the advent of Babinski's fundamental finding of the 'upgoing great toe' when the sole of the foot is scratched or stroked. This sign became one of the most important in clinical neurology. Babinski's sign is always pathognomonic of some involvement of the pyramidal pathway, except in very rare instances when none of the extensors of the great toes are involved and all its short flexors are paralyzed by spinomuscular (also called lower motor, peripheral, nucleomuscular) neuron involvement, and in the case of infants up to the age of walking. Until this time the presence of a Babinski sign is suggestive of nonmyelination of the corticospinal fibers. It might be mentioned here that infants may, and frequently do, suffer from lesions of the pyramidal tract, and that problems of differential diagnostic importance may be encountered in them.

In passing, we may mention that there are short-lived Babinski signs, e.g., during general anesthesia, poisoning with barbiturates or with the belladonna group—especially scopolamine—during insulin and uremic coma, during Cheyne-Stokes' respiration, in normal sleep (?) following convulsive seizures—idiopathic or otherwise—and in the wake of artificially induced convulsion. In these cases it is supposed that anoxia or some other transient interference with the pyramidal function produces temporary inactivity.

Technic of Elicitation—No matter how objective a certain sign may be it cannot be evaluated as easily as, for example, a chemical reaction as long as it must depend on some activity on the part of the physician. This is one of the reasons why time and experience are required before we can confidently state whether or not a certain reflex is

elicited. There is no problem to solve when any of the pathologic reflexes is fully developed. Lack of evaluation of the minor signs and improper technic are causes for misinterpreting a reflex.

It is generally accepted now that the responses to the Chaddock, Oppenheim and Gordon techniques are nothing more than the Babinski sign elicited from different parts of the wide receptive field for the "upgoing toe." However, exact knowledge of the technic of their elicitation is not without benefit to our diagnostic skill. The soles of some patients are so tender or are injured in such a way, as to prevent the examiner from touching them. In such cases the other techniques might be very useful. Besides, if we elicit dorsiflexion of the big toe with more than one technic, we are more fully convinced that we are dealing with a lesion of the pyramidal tract.

In trying to explain the techniques of elicitation of the pathologic reflexes which are generally used at the present time, I shall deviate somewhat from the usual presentation and submit the techniques as they have proved most dependable in my experience. In every instance I shall give the technic or techniques which, according to my investigation, have been most satisfactory in eliciting responses, even in their slightest manifestations.

The time has arrived for establishing a standard reflex technic. This would assist physicians everywhere to understand a certain technic and to evaluate and interpret the responses more uniformly. There is lack of uniformity in the clinical examination, as well as in the important animal experimentations. I know only too well that absolute uniformity cannot be achieved, but this should not deter us from attempting to reach such a goal.

Plantar Responses—I prefer a simple pin for eliciting the plantar responses, although a wooden applicator or match may also be used. Chaddock recommended a moderately pointed nail file. It is advisable to use the same type of instrument and to become accustomed to its use. Many contraptions have been recommended, and, in an attempt to standardize the method, "special stimulators" have been designed, but none of them has been generally accepted.

The *recumbent position* of the patient is best for eliciting the plantar responses. The patient is asked to relax if there is no unsurmountable spasticity or he is not unconscious. In the great majority of cases, withdrawal of the limb can be expected, it is, therefore, advisable for the examiner to grasp the leg of the patient just above the instep. This will guard against excessive withdrawal and will keep the foot in a position so that the movements of the toes may be observed to best advantage. The elicitation of responses is begun slowly from the

els forward, at first using slight stimulation, and holding the pin most parallel with the sole of the foot. In this manner unsightly scratch marks on the sole of the foot are eliminated. If there is no response to mild stimuli, or if the sole is calloused, stronger stimulus needed. In such cases the point of the pin becomes very handy. If slight stimulus does not suffice it is strengthened gradually until a flex movement is noticeable. Ankylosis in the metatarsophalangeal joint of the big toe and extreme spasticity of the muscles of the foot prevent any movement of the big toe. Athetoid movements may greatly interfere with correct interpretation of the direction of the toes.

Fig. 15.—The optimum location and the direction of stimulus for the elicitation of the Babinski sign.

The manifestation of the physiologic plantar reflex is the plantar flexion of all of the toes in the metatarsophalangeal joints. This flexion is quick and almost always accompanied by flexion movements of the ankle, knee and hip joints, as well as by contraction of the calf muscles and of the tensor fasciae femoris muscle. The normal plantar response is best elicited from the mesial border of the sole. On the other hand the optimum location for the elicitation of the Babinski sign is from the lateral border of the sole (Fig. 15). The normal response and the Babinski sign if well developed, may also be obtained by stimulation of any part of the sole.

The elicitation is begun with a mild stimulus, striking from the heel upward to, but not including, the ball of the foot, describing an inward curve just before reaching the base of the toes. If there is no response after repeated strokes, applying more force to each consecutive stroke, only then may we state that the Babinski sign is absent. Any differences between the two sides should be noted, as well as differences between the successive responses on one side, that is, the "upgoing toe" may alternate with the plantar flexion. In the early stages of pyramidal tract involvement, these minor alterations may be the first signs of beginning loss of function of the tract. When the Babinski sign is fully developed, it manifests itself in slow and forceful dorsiflexion of the big toe. Great care must be exercised not to interpret protective movements of the toes as reflex movements—this may not always be an easy task.

Frequently, we may also observe a spreading (fanning) of the other toes simultaneously with the "upgoing toe." The direction of these outer toes is generally horizontal, but they may turn downward or upward. At times all five toes dorsiflex without spreading. Very frequently, in addition to the toe movements, there is dorsiflexion in the ankle joint and flexion in the knee and hip joints. Contraction of the calf muscles and of the tensor fasciae latae can be observed most frequently, if we are looking for it. These widespread movements constitute the reflex flexion-defense withdrawal of the limb. According to the most widely accepted conception at the present time, the dorsiflexion of the big toe (still referred to as "extension" in general usage and in many textbooks) is but a component part of this defense reflex. Whether or not this is true, the fact remains that the most important and only definite pathognomonic movement is the dorsiflexion of the big toe. Flexion movements in the other joints, as already mentioned, occur also in the absence of pyramidal involvement.

It is of importance to know that in definite lesions of the pyramidal pathways we may encounter plantar flexion of the toes, including the big toe, by correctly executing the Babinski maneuver. Many neurologists consider this phenomenon as a sign of very severe and irreparable damage to the pyramidal tract. My own experiences with gunshot and stab wounds of the spinal cord during World War I are in accord with this observation. If the patient survives for a few months this plantar flexion usually changes to dorsiflexion.

Chaddock's Technic—Among the confirmatory methods, Chaddock's technic is the most sensitive. It consists in stroking the skin around the external malleolus in a circular direction, as depicted in Fig. 10. This single stimulation includes two separate areas originally recom-

nended by Chaddock as being the most sensitive for the elicitation of the reflex. The technic is to begin with a slight stimulation, stead

Fig 16—Chaddock's technic for elicitation of the pathologic plantar response.

Fig 17—Oppenheim's technic

ily increasing it until the pressure reaches its maximum at the end and maintaining this pressure for a few seconds before removing the

stimulator If there is no response, the force of the stimulation is increased from the beginning of its application to the end This stimulated area is much less sensitive than the sole, therefore, the stimulus used in the Chaddock technic, besides being an indicator of pyramidal involvement if the big toe dorsiflexes, also decreases the voluntary withdrawal movements of the limb to a great degree It is well to repeat the maneuver several times before declaring that there is no response It may be that the "summation" of stimuli explains that fact that occasionally, when the first applications do not evoke a response, the consecutive ones will, especially if the pressure is increased These observations are valid concerning the other technics also

Fig 18—The technic of Gordon

Oppenheim's Technic.—The next technic in frequency to indicate pyramidal fiber involvement is the technic of Oppenheim (Fig 17) Theoretically, in this technic the leg is divided into three equal sections and stimulation is begun at the top of the middle third The thumb is pressed firmly on the inner border of the tibia, with a downward stroke, until reflex toe movements are noted This usually occurs when the upper limit of the lower third is reached At times it is necessary to strike down to the internal malleolus with increasing force before the reflex can be obtained Only after repeating these manipulations several times, without a resulting dorsiflexion of the big toe, should we conclude that the Oppenheim method has failed

Gordon's Technic.—We are still using the Gordon technic routinely (Fig 18) but this may soon be discarded because this reflex is never present when those previously mentioned are absent. While we adhere to the technic for its elicitation, it is best to follow Gordon's original recommendation, namely, to stand at the outer side of the leg, rotate the foot slightly externally, press the fingers deeply upon the middle or lower portion of the calf muscles, simultaneously pressing with the thumb on the opposite portion of the same muscles. As in all previous technics, we consider the reflex sign to be present if the great toe dorsiflexes.

When extreme sensitivity of the patient interferes with the application of any of the mentioned technics I find it very helpful to divert the patient's attention from the manipulation by having him strain enough or breathe deeply.

Many other technics have been described. All of them have had a fair trial, but they have either not given positive results in a large enough number of cases or there were no benefits to be derived from their use so that they have become obsolete.

THE ROSSOLIMO SIGN

Not until Rossolimo described his sign did we have a really new contribution to the subject. This is not a modification of the technic of Babinski, but is an entirely different method of showing corticospinal tract involvement in the lower extremities. With this technic the tendons of the toes are primarily stimulated—shortened or lengthened. Thus the stimulus is proprioceptive in contradistinction to the Babinski method where the stimulus is exteroceptive. In addition, as will be explained, the responses to the stimuli are different. The Rossolimo sign can be elicited by (*a*) short, quick upward taps to the plantar surface of the toes, or (*b*) hitting the ball of the foot with a percussion hammer or (*c*) hitting the tips of the toes perpendicularly (Fig 19) with a sudden downward flap of the extended and stiffly held fingers, quickly withdrawing the hand so as to enable the examiner to observe the reflex movements of the toes. There will be no movement of the toes in healthy persons, or in extremely rare instances a slight dorsiflexion may ensue. However, in the presence of pyramidal tract lesions there is plantar flexion in the toe which has been struck or in the other toes also. At times only the outer toes flex in plantar direction or only the big toe flexes in this direction and at other times all the toes execute the same movement. All of these movements may be accompanied by slight abduction of the toes. A negative response should not be accepted until the above stimuli have

been repeated, with increasing force if necessary, using the different stimuli described above. The Rossolimo sign thus executed is a good

Fig. 19—One of the variations of the techniques for eliciting the Rossolimo sign—hitting the tips of the toes perpendicularly

test for proving pyramidal tract involvement. This sign may be present in many cases of early multiple sclerosis when the aforementioned signs are not, or are only equivocal.

THE HOFFMANN SIGN (INCLUDING TROMNER'S TECHNIC)

Thus far we have described only those signs which are definite indicators of pyramidal tract involvement. Before describing another reflex, which seems to be an even more sensitive test for detecting lesions of this tract, we shall mention the Hoffmann sign and clonus which may be obtained at times when there is no demonstrable lesion of the pyramidal tract. In a small percentage of men, when the Hoffmann or the Tromner technic is applied, we have noticed flexion of the digits in those exhibiting general hyperreflexia. This was found to be present in approximately 2 per cent of apparently normal college students. I have found this reflex in about the same percentage of otherwise healthy appearing men (ages 17 to 38) during induction for military service, and in a much greater percentage of patients suffering from idiopathic epilepsy (use of barbiturates?). In all these cases the responses were bilateral and equal. Naturally, slight symmetrical birth injuries or unobserved diseases of the central ner-

ous system could not be excluded in all of the cases. We should also consider this sign as a possible early indication of disease which has as yet no other manifestations. It would be a rare finding, however, if in any of these instances the Hoffmann sign were equal on both sides.

I have never missed finding the bilateral appearance of the Hoffmann sign after electrically induced convulsions. It lasts only a few minutes during the stage of flaccidity of the muscles. I emphasize this fact because many neurologists still believe that the Hoffmann sign

Fig. 20.—The technic for elicitation of the Hoffmann sign. Note the dorsiflexion of the hand.

is nothing but an indication of spasticity of the muscles. It is not a sign of spasticity, although spastic muscles greatly enhance the flexion movements of the fingers. I have had the opportunity to demonstrate the presence of this reflex in cases of unilateral flaccid paralysis as a definite sign of corticospinal neuron involvement.

Technic.—For obtaining the best results with this method, first dorsiflex the hand at the wrist joint (the dorsiflexion acts as reinforcement), then firmly grasp the middle phalanx of the semiflexed middle finger with two fingers (Fig. 20). Stabilizing the hand in this manner

been repeated, with increasing force if necessary, using the different stimuli described above. The Rossolimo sign thus executed is a good

Fig. 19—One of the variations of the technics for eliciting the Rossolimo sign—hitting the tips of the toes perpendicularly

test for proving pyramidal tract involvement. This sign may be present in many cases of early multiple sclerosis when the aforementioned signs are not, or are only equivocal.

THE HOFFMANN SIGN (INCLUDING TROMNER'S TECHNIC)

Thus far we have described only those signs which are definite indicators of pyramidal tract involvement. Before describing another reflex, which seems to be an even more sensitive test for detecting lesions of this tract, we shall mention the Hoffmann sign and clonus, which may be obtained at times when there is no demonstrable lesion of the pyramidal tract. In a small percentage of men, when the Hoffmann or the Tromner technic is applied, we have noticed flexion of all the digits in those exhibiting general hyperreflexia. This was found to be present in approximately 2 per cent of apparently normal college students. I have found this reflex in about the same percentage of otherwise healthy appearing men (ages 17 to 38) during induction for military service, and in a much greater percentage of patients suffering from idiopathic epilepsy (use of barbiturates²). In all of these cases the responses were bilateral and equal. Naturally, slight symmetrical birth injuries or unobserved diseases of the central nerv-

ous system could not be excluded in all of the cases. We should also consider this sign as a possible early indication of disease which has as yet no other manifestations. It would be a rare finding however if in any of these instances the Hoffmann sign were equal on both sides.

I have never missed finding the bilateral appearance of the Hoffmann sign after electrically induced convulsions. It lasts only a few minutes during the stage of flaccidity of the muscles. I emphasize this fact because many neurologists still believe that the Hoffmann sign

Fig. 20.—The technic for elicitation of the Hoffmann sign. Note the dorsiflexion of the hand.

is nothing but an indication of spasticity of the muscles. It is not a sign of spasticity, although spastic muscles greatly enhance the flexion movements of the fingers. I have had the opportunity to demonstrate the presence of this reflex in cases of unilateral flaccid paralysis as a definite sign of corticospinal neuron involvement.

Technic.—For obtaining the best results with this method, first dorsiflex the hand at the wrist joint (the dorsiflexion acts as reinforcement) then firmly grasp the middle phalanx of the semiflexed middle finger with two fingers (Fig. 20). Stabilizing the hand in this manner

proves to be of great benefit in observing the reflex movements of the other fingers. Next grasp the end phalanx of the patient's middle finger between the thumb and the index finger of the free hand and suddenly bend and release it (this is a modified technic of Hoffmann's, who never reported his reflex), or snap the palmar tip of the middle finger with a quick, firm upward flick (one of Tromner's many recommendations). The fully developed response manifests itself in an immediate flexion of the thumb and of all of the other fingers. *Many investigators, including myself, do not consider the Hoffmann reflex to be present if the thumb does not flex.*

To avoid confusion and to honor the man who first used it, we generally speak of this phenomenon as Hoffmann's sign. I have mentioned this sign as one which might be present only bilaterally in supposedly healthy individuals. Naturally, it might also be present bilaterally in a case of bilateral pyramidal tract involvement anywhere above the fourth cervical segment, but in this latter instance other concomitant signs of pyramidal tract disease will lead to a correct diagnosis.

If the Hoffmann sign is elicited properly and is obtained unilaterally only, it becomes the most sensitive sign of pyramidal tract involvement of the upper extremity. Several other reflexes are recommended for the purpose of diagnosing pyramidal involvement of the upper limb, but in my experience none—not even the Mayer sign—ever approaches the value of the Hoffmann sign. In many cases, in applying the Hoffmann technic, especially when there is spasticity of the muscles of the upper extremity, the whole arm jerks with simultaneous abduction of the shoulder and flexion in the elbow joints. I would like to mention a finding of mine which I have not seen recorded elsewhere, namely, that occasionally repeated and proper stimulation with the Hoffmann technic does not lead to flexion of the digits until the Tromner method has been applied immediately preceding the Hoffmann technic.

The hand area has a widespread representation in the motor cortex. The Hoffmann sign is diagnostic of a lesion in this cortical area and may point to the exact location, thus saving lives, e.g., by early removal of a neoplasm pressing upon the hand area. In such cases the Hoffmann sign is present without the Babinski sign.

CLONUS AND SUPRAPATELLAR REFLEX

To elicit the *ankle clonus* we bend the lower extremity in the hip and knee joints, and supporting the leg with one hand we suddenly dorsiflex the foot with the other hand, using moderate force. After reaching the maximum dorsiflexion the upward pressure is released

and thereafter moderate pressure is continuously sustained. If alternating plantar flexion and dorsal flexion of the foot ensue, we may state that ankle clonus is present. This clonus may be sustained or it may be of short duration. Many times when we are unsuccessful in obtaining a clonus in the manner described above, we may obtain it by holding the foot in a maximally dorsiflexed position and hitting the Achilles tendon with a brisk blow of the reflex hammer.

The *patellar clonus* is best elicited with the leg extended. The upper border of the patella is pressed suddenly downward with the thumb and forefinger, releasing the force of the downward pressure by holding the fingers steadily with moderate pressure. If alternating upward and downward movements of the patella follow, this indicates the patellar clonus. Occasionally, when this technic fails, I often obtain patellar clonus when I hit my forefinger, which is bent around the upper border of the patella, in a downward direction.

The *suprapatellar reflex*, which consists in an upward movement of the patella when the forefinger is hit in exactly the same manner as is described for the elicitation of the patellar clonus, is less frequently elicited than the regular patellar reflex. When bilaterally and equally present the suprapatellar reflex shows only general "reflex hyperirritability," but when present unilaterally it signifies a pyramidal lesion anywhere above the second lumbar segment.

The *wrist clonus* is found only in pronounced spasticity of the upper extremity. It is elicited by sudden dorsal flexion of the hand but clonus is not present until alternating upward and downward movements are seen.

THE GONDA SIGN

There are many controversial and unsolved problems in the interpretation and correlation of the findings in pyramidal tract involvement, e.g., it has not yet been definitely decided whether a certain part of the pyramidal system is involved when the Rossolimo sign is elicited and another when the Babinski sign is present. Some neurophysiologists have reported the finding of separate areas governing the "upgoing toe" part and the "fanning" component of the Babinski sign. It seems to me that as far as the Babinski and its related signs are concerned, 'organic' destruction or some temporary "functional" suspension of a certain percentage of the pyramidal tract fibers is necessary before pathologic signs can be elicited. This assumption might be of some importance for clinical and experimental purposes. If this conception could be considered as valid, then we could state that the Chaddock technic yields positive results with approximately the same extent of corticospinal involvement as the Babinski technic.

but the lesion must be more extensive for the Oppenheim or Gordon technic to result in the phenomenon of the "upgoing toe"

Fig 21—*Upper*, The technic and manifestations of the Gonda sign. Note the firm grip and twisting of the fourth toe. *Lower*, Occasionally only the flexing of all the outer toes results in dorsiflexion of the big toe.

Technic—In 1941, I described a sign and called it "tendon stretch reflex." Clinically and experimentally (in primates), this sign proved to be a more sensitive indicator of pyramidal tract involvement for the lower extremity than any of the previously described methods. The

ception I would not accept as confirmation of this statement the fact that prior to Tromner another neurologist stated that the tendons are only "conveyors" of the reflex mechanism. It was stated recently that the tendons are merely "dead tissue." They may be dead, but they have a nerve supply with special terminal fibers called the "organs of Golgi." It is easily conceivable that stimulation of these end organs in the tendons, even without any stretch of the muscles, might excite enough afferent impulses on the reflex arc to elicit a reflex.

Advantages of Method—Much study and experimentation will have to be done before this complicated problem will be solved scientifically. Meanwhile I should like to mention that this new technic, for the first time, led to a definite dorsiflexion of the big toe in lower primates (*Macaca mulatta*). In higher primates (chimpanzee), with experimentally produced pyramidal tract lesions, it is also a more sensitive sign than those used previously. It may be of great practical importance that in those diseases of the central nervous system in which other tracts besides the pyramidal system are also involved—e.g., amyotrophic lateral sclerosis, Friedreich's ataxia—and when the Babinski, its confirmatory signs and the Rossolimo sign may not be elicited, my method may be the only one which will definitely prove the presence of pyramidal tract lesions. Besides these advantages and those mentioned previously, it may contribute to the solution of the controversial question as to what constitutes the toe response in newborn infants and children up to the age when it changes to normal plantar reflex. And last, but not least, because this sign is never present in individuals not suffering from diseases of the pyramidal pathway, it will help more than any other method in making a differential diagnosis between organic lesions of the nervous system and symptoms caused by certain types of psychoneuroses or war neuroses. In these latter cases the deep reflexes may be exceedingly lively and paralyzes may appear which closely resemble "organic" palsies.

SUBDURAL HEMATOMA

ERIC OLDBERG, M D *

In this clinic I wish to describe and illustrate an entity which, despite its comparative frequency, still remains on occasion a neglected or unsuspected lesion for the general practitioner, and a difficultly diagnosed one for the neurologist or neurosurgical specialist. It is always on our "must" program for teaching medical students, and it fortunately falls into that category of cases, in our sometimes somber field, in which we may expect a large majority of complete and permanent cures if we can but be alert to and capable of recognizing the condition.

A subdural hematoma, as its name implies, is a hematoma which exists beneath the dura—between that membrane and the arachnoid. It is therefore separated from the brain proper by the pia, the arachnoid and the intervening space between these layers which contains the cerebrospinal fluid, and from the potential space between the dura and the bone of the skull by the dura mater. In this respect, its location is different from the position occupied by a meningeal arterial hemorrhage, an infinitely less common lesion, in that the latter almost invariably lies either outside the dura, in the space between that structure and the bone, or between the layers of the dura itself.

PATHOLOGIC FACTORS

For years subdural hematomas were confused pathologically with what Virchow had described as *pachymeningitis hemorrhagica interna* a condition of supposed spontaneous subdural bleeding occurring in alcoholics, demented patients, patients with conditions causing cerebral atrophy such as general paresis, and so on. Head trauma was regarded as a possible auxiliary factor, but it was Virchow's idea that the meningeal change, or meningitis, was primary, and that the bleeding was resultant and secondary. Since the time of Virchow this opinion has altered, so that it is now even doubtful that any such entity as described by him ever exists, at least in the manner he imagined.

Instead, a subdural clot is now generally accepted as having its

From the Department of Neurology and Neurological Surgery, University of Illinois College of Medicine, and the Illinois Neuropsychiatric Institute, Chicago.

* Professor of Neurology and Neurological Surgery and Head of the Department, University of Illinois College of Medicine.

origin in trauma, the meningeal changes being merely reactive phenomena. Those few exceptions which are unassociated with trauma are caused by vessel erosion from such a rarity, perhaps, as miliary meningeal carcinomatosis, but here again, the bleeding is primary as far as the formation of the condition is concerned.

The method of formation of subdural hematomas is interesting. They are usually confined to the convexities of the cerebrum, and most commentators agree that the source of the hemorrhage is from the fragile veins in the region of the sagittal sinus. Every neurological surgeon knows from experience that the tensile strength of the venous vessel walls in this region is so slight that the amount of direct trauma such as that from forceps or a cotton pledget, necessary to rupture them is almost infinitesimal. They are therefore situated and constructed in such a way as to be easily stretched and torn by outside trauma to the head, for on the one hand they are attached to the comparatively mobile brain which may be suddenly jolted out of position, while on the other they are connected to the relatively rigid sagittal sinus. That these lesions are almost unknown over the cerebellum is therefore explainable by the fact that no veins join its cortex to the median or straight sinus.

Trauma—This brings up the question of the amount of trauma necessary to initiate this pathological condition. It is a seemingly paradoxical fact that most of the cases of subdural hematoma that one sees clinically have resulted from rather trivial injuries. On the other hand, out of the plethora of cases of severe cerebral damage with skull fracture which constantly pass through our hospitals it is the exceptional patient who subsequently develops a subdural hematoma. Various explanations have been offered for this phenomenon, involving such things as individual variations in the tendency to bleed, in the constituents of the blood, and so forth. To me, the logical explanation seems to lie in two factors which have been elaborated by Putnam: first, that in severe injuries there is so much immediate edema of the brain that bleeding does not progress very far before it is stopped by pressure, and second and conversely, that when no such edema and pressure obtain, the brain sags away from the skull and dura when the patient is in an upright position, and thereby enhances the enlargement of the clot.

Whatever the cause we may say that it is not only possible but usual for comparatively minor injuries to the skull to be the cause of subdural hematoma. That they should occur more frequently in older individuals is readily understandable upon the basis of the increased fragility of the veins with age. This does not preclude their occur-

rence even in infants, however, upon whom reports have been made by Peet and Kahn, Naffziger, and others

Process of Formation—When trauma to the head occurs sufficient to rupture one or more of the veins traversing the subdural space on their way from the cortex to the sagittal sinus, the first thing which takes place is the extravasation of blood into the subdural space, and the formation thereby of a thin but extensive clot. This clot will almost always cover the whole of one hemisphere, and in some instances both hemispheres, if veins on both sides are torn. In a small proportion of such cases, the clot then becomes completely organized without liquefying, and the blood cells contained in it are destroyed in the process. In another small proportion, a minimal amount of blood becomes very largely mixed with cerebrospinal fluid escaping from a rent in the arachnoid, and such collections of fluid, becoming encysted in fibrin and mis-called subdural hygromas, may occasionally remain in status quo for years. This fact has been pointed out and well substantiated by Munro and Merritt.

In the great majority of cases of subdural bleeding, however, the resultant clot undergoes a series of interesting pathological steps. First, as in all clots, it becomes encased in a layer of fibrin which precipitates from it and surrounds it, the center becoming liquid through disintegration. The contiguous dura, which forms the parietal boundary, then begins proliferating fibroblasts, a layer of which eventually sweeps around the entire clot, invading the fibrin. This layer of fibroblasts is thick and finally becomes vascularized at its attachment to its dural source. The distant layer springing from the same source, and covering the visceral boundary of the hemorrhage, remains thin and avascular, however, for it is contiguous to the arachnoid which is devoid of blood supply.

The entire original clot, then, becomes a closed sac composed of semipermeable, dialyzing membrane, containing within itself a liquefied protein substance which is constantly breaking down through disintegration and producing a material of great osmotic differential to cerebrospinal fluid, and separated from that liquid only by the thin arachnoid and a thin fibroblastic layer. The result, of course, is that cerebrospinal fluid dialyzes through until the osmotic pressure of the hematoma fluid and the spinal fluid has equalized.

It has been estimated that this process continues for about three months, and the gradual growth by such a method of this "tumor" would explain the slow progressive symptoms of the disease. Certain it is that almost every hematoma one operates upon is startlingly enormous. At least one hemisphere is usually completely covered, and

mass thicknesses of two inches are not uncommon. There is a disparity in report as to the percentage of bilaterality, but I would estimate it to be 20 to 25 per cent.

Surgical Pathology—When the dura over such a lesion first comes into view it has a peculiar bluish hue, which is apparent through even so small an opening as a burr hole. Upon opening the dura, a greenish membrane is encountered which is more or less attached to it, of course by organization of fibrin. The greenness of the membrane has often been remarked upon, and has been attributed to transformation of blood into bile pigment by the reticulo-endothelial cells in the dura. When this green membrane is perforated, the liquid and major portion of the hematoma gushes out by the ounce, the color varying all the way from moderate xanthochromia to almost ink black. This discloses the greenish, thin, opalescent membrane of the visceral portion of the sac lying loosely and unattached upon the arachnoid. Removal of it reveals the normal, intact arachnoid.

CLINICAL FEATURES

How does all the foregoing discussion influence the clinical features associated with subdural hematoma? First, there will usually be a history of *injury to the head* more often than not of insufficient severity to produce unconsciousness. Sometimes this history of trauma cannot be obtained, either because the patient has forgotten it and his relatives have not known it, or because the patient has become mentally aberrant. I, myself, have seen two successive patients from whom no traumatic history was obtained, who, when mentally reoriented following operation, recollected having bumped the tops of their heads against automobile doorways when mounting the running board, and I have seen another who did the same against the door at the head of his basement steps.

Following the injury there will be a *latent period*, usually lasting from two or three weeks to several months. During this time the patient may feel perfectly well, or, as is more often the case, he will have no complaint other than that of a dull and rather persistent headache. Then symptoms definitely attributable to direct cerebral embarrassment begin to appear. These may present themselves as focal and purely neurologic findings, but in my experience the commonest initial cerebral manifestation is *mental aberration*—aberration of no special variety but taking the form of a new-found silliness, forgetfulness and untidiness. This experience is borne out by the fact that routine autopsies upon patients committed to hospitals for the insane always

show their quota of unsuspected subdural hematomas, the figures sometimes running as high as those reported by Allen, Daly and Moore in 1935, showing 245 cases in 3100 consecutive autopsies upon psychotic persons

Other than or in addition to psychosis, or at least deterioration, the neurologic symptoms may be legion, as would be expected of a lesion covering such an enormous territory as an entire hemisphere, and sometimes both hemispheres. These symptoms may be not only more or less cortical, as would be evidenced by such conditions as aphasia or hemiparesis, but they may be bizarre—homolateral paralysis sometimes occurring because of pressure of the opposite cerebral peduncle against the edge of the incisura tentorii, or homolateral homonymous hemianopsia being produced by impingement of the lateral geniculate body upon the same structure. In general, however, the definite neurologic symptoms will be accompanied by clinical signs which, when integrated, will prove logical and will provide clues indicating the underlying pathologic condition.

Clinical Signs—In the description of the clinical signs of a condition which reveals itself in such a multiplicity of ways as does subdural hematoma, it is difficult to decide upon a proper order of presentation. First, of course, comes objective evidence of *mental aberration*. Perhaps next most common is the evidence of *long-standing increased intracranial pressure*. This can be determined in the usual way by the examination of the optic fundi and, in addition, can be corroborated by lumbar puncture. Usually one abjures lumbar puncture in the presence of choked disk, but in suspected hematoma it is valuable because the discovery of xanthochromic fluid greatly aids in the diagnosis, though it is not necessarily present, and because a normal fluid pressure in association with intermittent stupor, headache, and so on, is also significant owing to the frequency with which it occurs—usually in old clots to which the brain has more or less accommodated. *X-ray examination of the skull* is also important for, if the pineal gland should happen to be visible, it has been said on good authority to be pushed further out of position by hematomas than by any other single type of lesion. In addition to these general signs, there may be various focal ones, the most common in my experience, being aphasia and mild signs of hemiparesis such as central facial weakness and characteristic reflex changes.

CASE REPORTS

The following cases illustrate the condition and manifest certain typical variations of it. The first example is an ordinary one with a

successful conclusion, and I would say that it represents fairly well 75 per cent of the cases encountered

CASE I—This patient was a 40 year old dock foreman, whom I first saw some six weeks after the date of his injury. The injury had occurred when the patient stepped upon a slack cable, which was suddenly tautened by a donkey engine, tossing the patient some 10 feet in the air and somersaulting him to the wooden flooring of the dock. The patient's head was severely bumped, but he was not knocked actually unconscious and was only dazed for a few minutes. He was taken to the hospital by the company physician, where x-ray plates of the skull were taken which revealed no abnormality and a midline pineal body. The patient remained at home for a week during most of which time he was up and about the house and he then returned to work and worked steadily for three weeks, although during this time he complained of ceaseless headache, which gradually became more severe as time went by. Finally it became so severe that the patient was again advised to rest at his home and this he did for a week, being out of bed a good deal of the time but the increase in his discomfort became so great that he was rehospitalized and had been so for one week at the time I first saw him.

At this time the patient was normal neurologically and skull plates had not been repeated. The optic fundi showed no sign of pressure, but a lumbar puncture yielded clear and colorless fluid under the moderately elevated pressure of 275 mm of water.

Three days later a second puncture showed a pressure of 350 mm, and in three to four more days the patient developed bilateral early papilledema. He also became somewhat aphasic and euphoric, developed a slight right lower facial weakness and x-ray plates of the skull showed a 2 cm shift of the pineal body toward the right.

A left parietal bur hole was accordingly made, and the dura opened and a large subdural hematoma identified. A moderate-sized centrally placed osteoplastic flap was therefore reflected, and it was obvious that the hematoma covered the entire convexity of the hemisphere. It was about 3 cm in thickness and when evacuated the yellowish cortex of the brain fell away from the inner table of the skull quite markedly. The patient was given 1000 cc of half-normal saline solution intravenously and placed in bed with the foot of the bed elevated and the patient lying on his left side.

Within a week the optic fundi, aphasia, mental change and facial weakness had all disappeared. The spine was repunctured on the eighth postoperative day and the pressure seen to be normal. The patient was up and about on the ward several days before his discharge, two weeks from the day of his operation. Within three months he was back at work, and he continued at this occupation for ten years until he finally died of cardiorenal disease.

Not all patients attain the happy result of Case I, however I would say that one of the most dangerous and difficult problems with which the neurosurgeon has to deal is the situation in which he is forced by circumstances to take immediate action in a case in which active bleeding may still be in progress. Case II illustrates why I have taken the stand that under all circumstances, even in the face of our usual dictum against moving head-injury patients, I must operate in such situations in my own hospital with my own staff. The time element alone, if spent waiting for a willing but unfamiliar nurse to respond to one's needs and wishes, may swing the balance.

CASE II—This patient, a 52 year old hospital superintendent, was seen ten days after his injury. The injury had occurred in an automobile collision in which the patient, who was driving his car, collided with another and bumped his head against the windshield, producing about one-half hour of unconsciousness. On regaining consciousness the patient drove his own car to the hospital of which he was superintendent and received first-aid therapy, had x-ray plates of the skull taken, which were negative and in which the pineal body was not calcified, and rested a few hours. On the following day he returned to work and worked for several days, despite an increasingly severe, generalized headache. This finally grew to be of sufficient proportions to produce vomiting on a couple of occasions and the patient, therefore, reentered the hospital, where he had been for three days prior to my visit to him on the tenth day after his injury.

On this visit the patient was sitting on the side of his bed with a table drawn in front of him and was signing the pay checks of the various hospital employees. He was alert mentally but complained of terrific headache. There was bilateral early papilledema but otherwise the patient was neurologically negative. He had been a known hypertensive for a number of years, and his blood pressure was 200/110.

A spinal puncture was performed which yielded xanthochromic fluid under a manometric pressure of 500 mm of water. Within forty-eight hours the patient's headache had increased to an almost unbearable point, and he was becoming stuporous. This progressed so rapidly that by the time operative arrangements were completed and I could arrive at the hospital with instruments, which was about two hours, the patient was in coma. A burr hole was placed over both parietal areas, about 3 cm from the midline, and a bilateral subdural hematoma was disclosed.

There was a thick, red clot and, in addition, continuous bleeding which it seemed impossible to stop. It finally did cease, however, after the patient's blood pressure had dropped, and a small piece of muscle was implanted in the hope that this would help prevent further bleeding. Within eighteen hours, however, the patient, who had not re-

gained consciousness, went into extremely deep coma, his blood pressure rose to 240/140, and his temperature began to rise, having reached about a degree above normal at the time I was called. He was accordingly transferred to my hospital by ambulance immediately, while the operating room was made ready. I reentered the old operative incision about twenty-four hours from the time of the previous operation, and on opening up the field was again met by profuse and uncontrollable bleeding. The patient had a convulsion on the table, his blood pressure rose to unmeasurable heights, and finally, after removing bone with rongeurs bilaterally toward the sagittal sinus, and using hot water irrigation, muscle and fascia implants, a reasonable degree of hemostasis seemed to have been obtained. The patient, however, did not show any improvement and expired overnight. Autopsy permission was granted, and it revealed that large veins on either side of the sagittal sinus had been completely sheared off, leaving apertures like portholes in the sagittal sinus.

For the reason so dramatically and tragically illustrated in Case II, it is well, as with brain abscesses, to wait a time when possible, and not to take action, especially early, until one is certain that the die is cast and escape impossible. Case III illustrates a somewhat rare but not impossible example of spontaneous remission.

CASE III—This 26 year old patient was struck on the head with a packing case, was not knocked unconscious and continued to work, but in a period of twelve to fifteen hours he developed such a severe headache that hospitalization was deemed necessary. This was done and the patient continued to lie in bed without displaying any objective localizing neurologic signs. A lumbar puncture performed on the fifth post-traumatic day yielded xanthochromic fluid under the markedly elevated pressure of 500 mm. of water. I saw the patient two days following this and a second puncture was performed, yielding fluid which was still xanthochromic but in less degree and the pressure of which was 250 mm. At the time of my visit the patient complained of headache and stiff neck, but there were no neurologic findings whatever except for some slight engorgement of the optic fundi.

The patient improved gradually, and a spinal puncture done on the twelfth post-traumatic day yielded very faintly xanthochromic fluid under a pressure of 200 mm., and another puncture done five days later yielded clear and colorless fluid under the slightly high normal pressure of 170 mm. of water.

The patient continued to improve rapidly, and when last heard from was perfectly well and without disability.

Case IV is included in order to emphasize that we should not, in medicine, allow ourselves in our wish for simple explanations to be car-

ried to the absurd. It is obvious from contemplation of the manner of formation of subdural hematomas that they are dynamic and not static lesions. Symptoms from them increase, and I often oversimplify to medical students by saying that "patients with subdural hematoma are almost always either dead or operated upon within six months." Yet a certain number of cases are seen by me each year, some with medicolegal complications, in which this diagnosis has been made and insisted upon by some well-meaning physician, as long as three to five years after the alleged etiological trauma. I would say the case to follow is an average example.

CASE IV.—This patient, a 50 year old wife of an accountant had been in an automobile accident sixteen months before she was referred to me with the diagnosis of subdural hematoma, this being based upon a history of persistent headache, positional dizziness and generalized lassitude. At the time of the injury the patient had been rendered unconscious for a period of two hours, and had remained in the hospital for six weeks in the small town in which the accident happened. Following her return to her home in Chicago, the patient remained in bed and had a practical nurse for several weeks subsequently. She then began gradually to get up and about but she developed a marked fear of any strenuous activity, either mental or physical, because this apparently increased the discomfort, and as a result lived as a semi-invalid. This state of affairs continued until a year had elapsed, after which time symptoms began to increase slightly and the patient spent considerable time in bed. She had passed the menopause five years previously. She had no children, and her husband seemed to be a somewhat oversolicitous type. The patient had been examined by a number of physicians and had been out of the city to a couple of large medical centers before being referred to me.

In view of the long history and the obvious fact that the patient and her husband needed to be satisfied in their minds that no serious surgical condition was developing, the patient was admitted to the hospital. She complained considerably and required a good deal of analgesic and sedative medication. Complete neurologic examination and examination of the optic fundi were all normal. X-ray plates of the skull revealed no abnormality and no evidences of fracture, old or recent, and the pineal body was calcified and lying in the normal position in the midline. Lumbar puncture yielded clear, colorless fluid under the low normal pressure of 110 mm. of water, in which all findings were completely within normal limits.

It was explained to the patient and her husband, as well as to the referring physician, that no space-occupying lesion, such as a subdural hematoma, seemed to be present, and that the symptoms, which for a time had undoubtedly been genuine following the patient's moder-

tely severe head injury were now rapidly approaching in entirely functional state. The matter of encephalography was also discussed, and all concerned were informed by me that there was some psychological risk in performing this procedure on this type of patient since, if it did not help considerably, it might very likely do the opposite. Because nothing very constructive with regard to management of the case could be reasonably expected with this procedure, it was decided to abjure it. After a thorough medical elimination of other possible causes of headache, psychiatric consultation was called and at last hearing was still proceeding intermittently, several months after I saw the case, with a moderate degree of success. The patient at first resented the thought that her complaints might not be organic in nature.

My final protocol concerns a kind of experience which, for all our vigilance, occurs with distressing regularity each year. However, such an experience does have a three-fold good effect. First, it helps to keep us humble. Second, it reminds us to think long and carefully before resigning ourselves to inactivity in the face of impending death and bolsters our morale when we advise stricken families to have a simple exploration, even when we know how high are the probabilities of fruitlessness. (This does not mean that we, for instance, advise decompression for some such lesion as tuberculous meningitis, but only that no matter how strongly we feel we will encounter a glioblastoma in a patient with a rapid history of an expanding lesion, our consciences must demand confirmation, for sometimes we are wrong.) And third, providence seems to balance those cases we neglect from ignorance with others, equally unsuspected and unexpectedly hit upon, in the face of apparently overwhelming odds.

CASE V.—This patient, a man of 65, had been an enigma at the hospital in which he was a patient. He had been seen by several leading neurologists, and opinions were evenly divided as to whether he suffered from some diffuse encephalitic process or a malignant glioma of the brain. Several spinal punctures had been performed, the dynamics chemistry, serology and cell count of which had been normal, x-ray plates of the skull were also normal except that the pineal body, which was in the midline, was interpreted as being slightly depressed. When I saw the patient, he had been ill in the hospital for about two weeks and had been in coma for several days. There was a complete right hemiplegia and a complete aphasia had existed prior to the onset of coma. The blood pressure was low, and spinal fluid pressure on punctures had never shown any increase in intracranial tension, as stated above. The lesion had been progressive, as far as the history was concerned, over a number of weeks. The family gave no

history of any antecedent history, therefore, in view of the rapid progress of the lesion, I felt it was probably a malignant infiltrating glioma, which was destroying brain tissue rather than pushing it to one side and creating edema and, as sometimes happens with such cases, there was no increase in intracranial pressure and no great pineal shift

Following my visit the patient remained in a precarious condition and finally expired in about a week. Autopsy permission was obtained and a bilateral subdural hematoma was disclosed, which was larger over the left hemisphere than over the right. The family then remembered that the patient about two months previously had come home from his work, which was that of laundry man, and had complained that he had been in a minor automobile collision and had been thrown against the metal roof of the cab of his delivery truck. In view of the pathologic nature of the lesion, double indemnity was awarded in the case of this death on the ground that the lesion was necessarily post-traumatic, whether the original trauma had ever been officially reported or not.

SUMMARY

I have attempted to make clear the manner of formation and the clinical manifestations and vagaries of this interesting and not uncommon condition. Bear in mind the surgical pathology of its development, the dynamic nature of its progress and the paradox of its appearance in mild rather than severe head trauma. Only thus can we conscientiously discharge our duty to our patients, and, we hope, maintain a high diagnostic batting average. It is worth it.

THE RELIEF OF FACIAL PAIN

A LARI WALKER, M.D.*

A discussion of facial pain based upon the location of the pathologic change is not entirely satisfactory from the clinical standpoint. The etiology of too many cases of pain in the face is still obscure. A much more valuable classification is based upon the description of the pain which frequently is so typical that a clinical diagnosis may be made from the history. This is particularly true when considering the surgical relief of facial pain, for certain trigeminal neuralgias with distinct clinical characteristics are amenable to operative procedures, whereas other neuralgias of the face clinically differing from the first type only in the description of the pain are not affected or may even be aggravated by such surgical therapy.

TRIGEMINAL NEURALGIA†

Symptomatology—Trigeminal neuralgia is a distinct clinical entity characterized by severe paroxysmal pain confined to one, two or three divisions of the trigeminal nerve without sensory or motor disturbances in the face. The paroxysm is described as a sharp, shooting, darting, stabbing, burning, cutting, tearing, grinding, boring or jabbing pain in the teeth, jaw, cheek, eye or temple lasting only a few seconds. The spasmodic nature of the disease with practically complete freedom between the crises except for perhaps a slight soreness in the face is an essential feature of the condition (Fig. 22).

Initially the pain usually occurs spontaneously in the upper or lower jaw. Commonly it is referred to a tooth, which though it be pronounced healthy by the dentist, is finally removed at the insistence of the patient. Unfortunately, relief from such measures is not forthcoming, for dental disease is not an etiologic factor in this condition. The pain gradually increases in frequency and radiates over a wider area to the cheek, tongue, lips or lower jaw. With increasing paroxysms the pain tends to spread, although for years it may be confined

From the Division of Neurological Surgery, the University of Chicago Clinics, Chicago.

* Associate Professor of Surgery (Neurosurgery), University of Chicago School of Medicine.

† This condition is also called trifacial neuralgia, tic douloureux, epileptiform neuralgia, Fothergill's disease, neuralgia major and prosopalgia.

to one division of the trigeminal nerve, usually the third, occasionally the second and rarely the first

Trigger Zones—The patient soon recognizes that a paroxysm may be set off by mechanical irritation of a small area of skin of the face or mucous membrane of the mouth. Merely touching these "trigger zones" or "dolorogenetic areas" will induce an agonizing paroxysm. Usually the trigger zones are situated about the lips, the nose or on the alveolar margins of the jaws. The pain induced by stimulation of

Fig 22—An artist's phantasy depicting the horrors of trigeminal neuralgia (From a lithograph by Alexander Ver Huell)

the trigeminal nerve may be referred to areas quite distant from the situation of the trigger zone, even to a completely anesthetic area. Thus the trigger zone may be in the upper lip, while the pain is in the forehead or lower jaw. Even a breeze blowing on the face may be an effective stimulus so that the patient wears a shawl. Washing the face may induce such agonizing pain that dirt is allowed to become matted on the cheek. The irritating stimulus need not be exogenous. Chewing, swallowing, or movements of the tongue may be quite adequate to bring on a paroxysm of pain. As mute evidence of this, in

patients suffering from neuralgia of the third division, the affected side of the tongue may be markedly furred as compared to the clean surface on the other side. The agony of eating is such that these sufferers rapidly lose weight due to inanition and dehydration.

Diagnosis—The history is practically pathognomonic of the condition—indeed, since there are no constant abnormal neurologic or physical findings, the diagnosis must be based upon the history. The condition is characterized by remissions which may last months or even years. Not infrequently during the summer or winter the patient is free of pain, only to suffer again with the change of weather.³¹ Strangely enough the right side of the face is affected more frequently than the left. The condition occurs more commonly in the female than in the male, but is almost invariably found in the latter half of life. Occasionally it is encountered in a young individual, but in such cases one is always suspicious that it is symptomatic of another intracranial condition. In 2 to 5 per cent of cases^{9, 14} the condition occurs on both sides of the face, usually not simultaneously.

Symptomatic Trigeminal Neuralgia—Occasionally facial pain identical with that of *tic douloureux* may occur as a manifestation of another disease of the nervous system. Paroxysmal facial pain is encountered in *multiple sclerosis* more frequently than the chance coincidence of the two diseases. A plaque in the spinal root of the trigeminal nerve is present in some of these cases, and is thought to be responsible for the pain. *Syringomyelia* or *syringobulbia* may also have, as a symptom, attacks of facial pain presumably due to involvement of trigeminal nerve centers by the syrinx. Another disease in which typical trigeminal neuralgia may appear as a symptom is *tabes dorsalis*. One might consider the facial tic as a lightning pain but coincident pains in the extremities are infrequent. Rarely, one of the first manifestations of a *neoplasm in the cerebellopontine angle* will be typical paroxysmal trigeminal pain. Symptomatic trigeminal neuralgia usually may be clearly differentiated from the essential variety by the presence of neurological changes and in particular by sensory disturbances in the distribution of the fifth nerve. Such alterations in nervous function in a patient suffering trigeminal neuralgia should lead one to search carefully for an intracranial lesion.

Pathogenesis—The pathological basis of trigeminal neuralgia has not yet been adequately established. Early it was assumed that the pain was related to vascular disturbances in the gasserian ganglion. Since the disease occurs predominately in older individuals who are likely to have moderate or severe arteriosclerosis, one would expect to find vascular changes in and about the gasserian ganglion. However such

alterations are no more pronounced in patients suffering from trigeminal neuralgia than in patients of the same age group who die of other diseases. Moreover, many individuals suffering from trigeminal neuralgia have no evidence of arteriosclerosis or other vascular disease in or about the gasserian ganglion. It therefore seems difficult to give credence to this theory of the pathogenesis of trigeminal neuralgia.

It has been suggested that aberrant vessels passing across the trigeminal root between the pons and gasserian ganglion or sclerotic plaques in such vessels might irritate the nerve root. Dandy³ has particularly emphasized this view since in the cerebellar approach for the relief of trigeminal neuralgia he is able to visualize the structures about the trigeminal nerve better than those operators who perform the classical retrogasserian neurotomy. In 1932 he stated² that in patients with trigeminal neuralgia he had found a 12.5 per cent incidence of vascular abnormalities and a 5 per cent incidence of otherwise asymptomatic tumors in the cerebellopontine angle. Seven years later³ he reported that the incidence of tumor was still 5 per cent but that vascular anomalies were present in nearly all other cases. Most neurosurgeons believe that in the vast majority of cases of trigeminal neuralgia no gross pathological factor is known.

Lewy and others^{9, 20} suggested that pathologic changes in the thalamus were the basis of trigeminal neuralgia. However, this view has not been generally accepted, largely due to the fact that significant thalamic disease has not been found in the brains of patients who have suffered from trigeminal neuralgia.

TREATMENT

Principles—The therapy of this condition is directed to a diminution of afferent impulses reaching the central nervous system through the affected trigeminal nerve. This may be accomplished by drugs decreasing the conductivity of the trigeminal nerve, by blocking the trigeminal nerve or by anatomical interruption of the fibers of one or more branches of the trigeminal nerve. Although dental, sinus and other local facial lesions are not considered etiologically related to trigeminal neuralgia, it is advisable from the general medical standpoint to eliminate any infection in the mouth or sinuses. Sometimes such procedures will bring about a rather long-standing remission of the trigeminal pain. It should be emphasized, however, that such treatments should be made for the purpose of eliminating actual sinus or dental disease and not primarily for the relief of trigeminal neuralgia per se.

Medical Management

Drugs.—Medical management in early and mild cases may give slight relief. Recently Davidoff² has revived the old treatment suggested by Hutchinson, namely, the administration of *ferrous carbonate* in doses of 60 grains a day. The persistent use of this therapy is said to relieve trigeminal neuralgia but my personal experience with this medication is disappointing.

Thiamine hydrochloride has been suggested as a means of treating trigeminal neuralgia.¹ The results of this therapy when critically reviewed are not encouraging. It is said that the treatment must be given for several months before results can be expected, but knowing the tendency of trigeminal neuralgia to undergo spontaneous remissions, it seems likely that such remissions have occurred during the treatment of those patients who were said to have received benefit from vitamin B₁ therapy.²⁵

Once the paroxysms are established, medication is of no significant or lasting value. To tide the patient over a crisis until more adequate therapy can be administered, *trichlorethylene* may be of temporary value. The predominant effect of this drug on the trigeminal nerve was recognized during the first World War when occupational exposure to it was found to produce a numbness of the face. The usual method of treatment is to pour 15 or 20 drops of trichlorethylene on a handkerchief in a cone of paper. The patient, sitting or lying to avoid falling should lightheadedness develop, places his face over the open end of the cone and inhales until the odor has disappeared. If the inhalation is taken a few minutes before a meal, eating may be possible without discomfort. The patient should be warned that the drug should not be inhaled oftener than three to four times a day, for more frequent inhalations may produce an intoxication. One patient suffering from a severe trigeminal neuralgia was brought into the hospital in a comatose state. Her husband stated that because of the severe pain she had inhaled two or three 4-ounce bottles of trichlorethylene within a day or two gradually becoming more and more stuporous. It was several days before she recovered from her intoxication. While narcotics will relieve the pain, their administration is not advisable owing to the danger of addiction. This is particularly to be emphasized since such treatment may lead to a more difficult problem than the original complaint.

Alcohol Injections—For all patients whose pain is severe, the treatment of choice is interruption of the trigeminal nerve or its branches. This may be done by an alcohol injection of the peripheral nerves

the gasserian ganglion, or by surgical section of the root. Which of these procedures should be carried out is a question to be decided upon by the physician in each individual case. Alcohol injection produces a temporary paralysis of the nerve, with simultaneous return of the function and usually of the pain in three to eighteen months. Occasionally a gasserian ganglion injection will last many years¹⁴. If the individual has mild or infrequent paroxysms or shows neurotic tendencies, it may be wise to inject alcohol into the involved division or peripheral nerve to determine the patient's reaction to the resulting paresthesia. Not only is the individual given an opportunity to decide whether the numbness is preferable to the pain, but the surgeon may determine that a retrogasserian neurotomy will give relief. For this reason some operators are of the opinion that all patients should have a preliminary injection before surgical section. However, since the injection is not without pain or danger, a primary retrogasserian neurotomy is advisable in patients whose general physical condition suggests a life expectancy of more than five years and who are suffering severe paroxysms at relatively frequent intervals.

The following case illustrates the value of a preliminary alcohol injection.

E. P., a 52 year old locomotive fireman, was admitted to the University of Chicago Clinics on August 2, 1943. He complained of an aching, jerking pain in the left cheek of three years' duration. About one year after the onset of the symptom the patient consulted a dentist who, finding a "white spot" over the premolar teeth, extracted all his upper teeth. Relief not occurring, all the lower teeth were removed—but the pain persisted. In March 1943 the pain became so severe that he was unable to sleep at night. He was given a series of 22 "shots" in the right cheek, which relieved his pain for two weeks, but when it returned it was more severe than ever.

The pain was a constant ache fairly well localized to the left cheek near the temporomandibular joint. For periods of ten minutes to two hours it became sharper and jerking, after which it returned to a persistent ache. While it occurred at any time of the day or night, it was often brought on by talking, eating, wearing a denture or lying on that side of the face. Because of the difficulty in eating and sleeping, the patient lost 20 pounds in weight.

The past history and functional inquiry were not contributory.

The patient was a thin, edentulous male, whose physical examination revealed no abnormality. His memory was not good, but he blamed this upon loss of sleep. Neurologic examination otherwise was normal except for a slight hypalgesia over the left upper lip and cheek.

The diagnosis in this case was not clear. The patient's description of

his pain was not that of a typical trigeminal neuralgia. The exacerbations of severe pain brought on by talking, eating and so forth suggested tic douloureux, but the constant ache made the condition atypical. For that reason an alcohol injection of the nerve was advised as a therapeutic test.

On August 3, 1943 after anesthetizing a small area of the cheek, a needle was inserted through the foramen ovale to the gasserian ganglion. After injection of 0.5 cc of 1 per cent novocaine the skin innervated by the second division became anesthetic and following another injection of 0.5 cc of novocaine that supplied by the third division became hypesthetic. An injection of 1 cc of absolute alcohol was made and another injection of 0.5 cc after the needle had been withdrawn 1 cm. The patient experienced a burning sensation in the face as the injection was made.

On the following morning the sensory disturbances were less pronounced and largely confined to the area of innervation of the third division. The patient's pain was less, so he was discharged to return in one week. However, his pain returned and on August 6, 1943 another injection was made in the left gasserian ganglion, 1.2 cc of alcohol being used. An anesthesia of the second and third divisions was obtained. His severe pain was immediately relieved. One year later, August 2, 1944 he returned. His face felt numb and he had some paresthesias in the face, but none of the former severe pains. He still had practically a complete anesthesia of the second and third divisions of the trigeminal nerve with paralysis of the masseter and temporal muscles. He had gained weight and felt quite well.

This case illustrates the value of alcohol injection. Although the history of this patient was not quite typical of true trigeminal neuralgias, he obtained almost complete relief from interruption of the function of the fifth nerve. If this patient's pain returns, a retrogasserian neurectomy is contemplated. Such unusual cases of trigeminal neuralgia occasionally are seen. A block of the fifth nerve is necessary to establish the diagnosis and to be certain that nerve section will relieve the pain. Not infrequently the severe paroxysms may be abolished leaving the background paresthesias still present.

The alcohol injection may be made into a peripheral branch of the trigeminal nerve at the supraorbital, infraorbital or mental foramen, depending upon the location of the pain. If more than one division is involved, the gasserian ganglion must be injected. While it is possible to inject the third division alone at the foramen ovale, it is impossible to inject either of the other divisions or any two other divisions selectively with certainty. Injection at the foramen rotundum is too hazardous for routine use. One must then consider the probability that

the injection of the gasserian ganglion will produce a complete paralysis of the trigeminal nerve with anesthesia of all three divisions

The injection must be made when the patient is awake so that the position of the needle may be determined with certainty—by the injection of 0.5 cc of 1 per cent novocaine. Unless an anesthesia of the area innervated by the injected nerve is obtained, alcohol should not be used, for there is danger of injecting intracranial structures which may produce serious sequelae. Blindness, oculomotor paralysis and unilateral deafness are not unknown as sequelae of attempted alcohol injections of the gasserian ganglion. If the desired root or ganglion is not struck after three or four attempts, it is usually better to desist and attempt another injection at a later date since not only is the patient hurt by the attempts, but the novocaine injected infiltrates slowly into the tissue and may reach the nerve thus producing anesthesia when the tip of the needle is too far away for an alcohol injection to be effective. Usually 1 cc of absolute alcohol is all that is required for a good block of a peripheral nerve or the gasserian ganglion. In spite of the preliminary novocainization there is considerable burning pain as the alcohol reaches the nerve fibers. This disappears within a few minutes leaving the area anesthetic. Before carrying out the procedure it is frequently advisable to give the patient $\frac{1}{4}$ or $\frac{1}{6}$ gr (0.015–0.010 gm) of morphine. If the first division is rendered anesthetic by the injection, the cornea should be protected by an eyeshield as described later in this paper.

Surgical Methods of Treatment

Fifty years ago the surgical therapy of trigeminal neuralgia was largely confined to methods of sectioning or stretching the peripheral branches of the fifth cranial nerve.¹⁰ At about that time it was recognized that such procedures were quite temporary, for Horsley¹⁵ and Rose²⁰ were suggesting operations upon the trigeminal root and ganglion. Unfortunately the surgical technic then was not developed to a sufficiently high level that such operations could be performed safely. Surgical procedures upon the peripheral branches have been largely discarded except for the avulsion of the supraorbital nerve. This is still carried out in selected cases of first division pain when the condition of the patient precludes a more serious operation, or in cases in which the possibility of keratitis is to be avoided even at the risk of recurrence of the pain.

Classical Retrogasserian Neurotomy—The classical retrogasserian neurotomy (Spiller-Frazier operation) remains the safest and most certain method of surgical treatment of trigeminal neuralgia. The mortality

from this procedure is low (less than 1 per cent) and the morbidity slight. Ordinarily the period of hospitalization is not more than five or six days. It is possible selectively to cut any desired division or divisions of the trigeminal nerve and to leave intact the motor division. Thus, in the majority of cases, because the pain is confined to the lower part of the face, the first division of the trigeminal nerve is spared. If the section has been adequate complete relief of pain is obtained. Grant⁹ reported 949 operations with complete relief of the pain in 942 instances. In the seven patients having no relief, it was assumed that the pain was not that of trigeminal neuralgia and that operations should not have been performed. Such an error in diagnosis might have been avoided by a preliminary injection of alcohol into the appropriate branch of the fifth nerve.

OPERATIVE RESULTS—The most extensive report upon the operative results of retrogasserian neurectomy is Grant's compilation⁹ of the cases operated upon at Philadelphia the majority by the late Charles L. Razier. The figures presented here are based upon those data.

Recurrence—Following what was considered by the operator to be complete sensory root ablation the pain recurred in seven patients in the series of 359 cases (2 per cent). In the series of 590 patients in whom partial section was accomplished there were forty-four recurrences (7.4 per cent). In all but four of these cases the recurrence was in the first division which had been deliberately spared. Avulsion of the supraorbital nerve was sufficient to relieve thirty of these cases.

Paresthesias—Following retrogasserian neurotomy the majority of patients have little complaint referable to the anesthetic face. Approximately 13.8 per cent notice paresthesias, such as numbness, heat or cold, itching, drawing or twitching. In Grant's series 3.4 per cent had more severe paresthesias which were usually referred to as a burning itching pain. These paresthesias may develop immediately after the operation or occur at later intervals, but usually within the first year or two. Some of these patients will become so accustomed to the paresthesia that it does not bother them, but the majority continue to complain of paresthesias of greater or lesser severity. The relief of such disturbances is not very satisfactory. Secondary operations upon the sensory root do not relieve the pain nor has sympathetic surgery given good results.

COMPLICATIONS—**Keratitis**—Following complete section of the sensory root, keratitis results in approximately 16.7 per cent of cases and in approximately 10 per cent of these cases enucleation of the eye is necessary to control the infection. Following subtotal section of the root the danger of keratitis is much less—approximately 4.4 per cent—

and the severity of the keratitis is also less. The keratitis may result from involvement of the cornea by the herpes which frequently develops about the lips after operation or more commonly from trauma due to painless scratching of the cornea by dust or cinders lodging in the conjunctival sac. To avoid such a complication the patient should be advised to keep the eye protected by a shield attached to the rim of spectacles and snugly fitted to the contour of the orbit. To prevent fogging the lens, small perforations may be made in the shield or the glass treated by "antifrost." The patient should be advised to wash out the eye morning and night with a boric acid solution and to report to his physician if the slightest corneal injection develops. Unfortunately, some patients do not take this advice seriously. I had one patient who, instead of washing the eye out morning and night, would dab a piece of cotton into the solution and wipe it across the cornea. By such trauma he shortly developed a keratitis. If simple irrigations do not relieve the keratitis, it is advisable to suture the eyelids. Under no circumstances should a cotton pad be placed over the eye, for these patients are apt to open the eyelids, allowing the cotton to rub painlessly on the anesthetic cornea. Castor oil dropped into the conjunctival sac morning and night will keep the cornea moist.

Facial Paralysis—Facial paresis occurred in 3.4 per cent of Grant's cases. The majority of patients with this complication recovered completely within six months, but a few did not recover. It has been suggested that the cause of the facial paralysis may be either hemorrhages in the pons due to an avulsion of the sensory root of the fifth nerve or damage to the petrosal nerve or vein by stripping the dura mater from the floor of the skull. Gardner and Babbitt⁷ have noticed hemorrhages in the middle ear in certain cases complicated by facial paralysis.

Other Complications—Rarely the third, fourth or sixth cranial nerve may be damaged during a retrogasserian neurotomy. Since many of the patients are elderly, it is not surprising that occasionally a hemiplegia due to thrombosis or hemorrhage develops as a complication. Such vascular accidents are the usual cause of the rare fatality which occurs following the operation. In a few cases cerebral anemia due to a rapid fall in blood pressure during the operation with the patient sitting may produce symmetrical areas of necrosis in the paracentral region and later death from pneumonia. Rarely trophic disturbances develop in the anesthetic area of the face. Usually these are the result of chronic irritation of the skin or mucous membrane. The lesion is usually a necrotic area lined by granulating tissue. It responds poorly to any type of therapy (Fig. 23).

Posterior Retrogasserian Neurotomy—Dandy^{2 3 4} has utilized a sub-cerebellar approach for sectioning the posterior root of the trigeminal nerve, for he claims that following partial section by this route there is never corneal disturbance never loss of the motor branch, little, if any, loss of sensation in the face, rarely facial paralysis and severe hemiplegia. This method in the hands of a highly skilled surgeon would appear to have definite advantages but many neurological surgeons consider it technically more difficult and potentially more

Fig 23—Trophic disturbances about the nose of a patient following alcohol injection of the gasserian ganglion for the relief of tic douloureux. The patient was constantly wiping the nose on account of paresthesias.

dangerous than the classical retrogasserian neurotomy. The preservation of sensation in the face with complete relief of pain and infrequent recurrence (2 per cent) is much in favor of the operation, for it prevents the disagreeable paresthesias in the numb face. Hyndman¹⁷ finds that he can obtain equally good results with little or no sensory loss using the subtemporal approach and only sectioning a part of the posterior root of the trigeminal nerve. These observations suggest that the trigeminal root undergoes a rearrangement of fibers as it passes

from the gasserian ganglion to the pons so that the divisions are no longer separately or isolatedly grouped

Medullary Tractotomy—With a view to eliminating paresthesias in the face by sectioning only the pain fibers of the fifth cranial nerve, Sjoqvist²⁷ in 1938 introduced medullary tractotomy as a means of relieving facial pain. The operation is carried out by a suboccipital approach and the descending tract of the trigeminal nerve is sectioned near the level of the obex (Fig 24). Olivecrona²⁴ has reported upon the largest series of cases operated upon by this method. In thirty patients having unilateral trigeminal neuralgia he performed a medul-

Fig 24—A cross section of the medulla oblongata through the level of medullary tractotomy showing the area of the incision

lary tractotomy with no deaths. In eighteen cases an analgesia of the face resulted, in nine a hypalgesia and in three cases no sensory loss was detectable. The pain was relieved immediately in most cases but eight patients had a recurrence of pain, two of whom had a subtotal or complete analgesia of the face. The disturbances in appreciation of temperature did not parallel the pain loss. Some impairment of touch was usually detectable. In two-thirds of the cases disturbances of equilibrium were present, though usually transient. Grant and his co-workers^{10 11 12 29 30} had previously emphasized this complication in their series of fifteen cases. Both Grant and Olivecrona found that the

patients complained of paresthesias, in Olivecrona's series 16.7 per cent had such disturbances. But more important, eight of Olivecrona's series had unilateral paralysis of the vocal cords. Herpes labialis and keratitis were reported in Olivecrona's series. In four of Grant's patients hiccoughs were a troublesome, though temporary, complication. Olivecrona operated upon four patients suffering from bilateral trigeminal neuralgia, although in only three cases was the operation performed bilaterally. In the one unilateral and one bilateral case little or no relief was obtained but in the other two bilateral cases good results followed the operation.

Olivecrona's report appears to be fairly representative of the results obtained by other operators on smaller series of cases. Almost all neurological surgeons who have tried the procedure have had excellent results only in the majority of cases. For this reason both Grant and Olivecrona conclude that it is not ideal as a routine procedure for trigeminal neuralgia but that it has a definite place in the treatment of selected cases.

ATYPICAL TRIGEMINAL NEURALGIA

Atypical trigeminal neuralgia is a designation used to include many varieties of facial pain, which differ in some clinical respects from trigeminal neuralgia and which have no known etiology. They are frequently referred to as psychalgias because of their association with psychoneurotic manifestations. Although this type of pain may be as bitterly bemoaned as that of *tic douloureux*, frequently the calm mien of the patient seems to belie his complaints. However, in some cases the pain is so distressing and annoying that the patients threaten suicide, become drug addicts, or markedly psychopathic.

The main distinction between this group of facial neuralgias and typical trigeminal neuralgia is in the *duration* of the pain. While in *tic douloureux* the pain is paroxysmal, lasting only a few seconds, in atypical trigeminal neuralgia it tends to persist for relatively long periods of time, although there may be severe exacerbations for a few seconds or minutes. The description of the pain in the two conditions may be similar. In a typical neuralgia Glaser⁸ found that a dull aching pain is the most common description of the sensation, occurring in approximately 37 per cent of the cases, but many patients complain of a burning, throbbing, shooting, sharp, boring, drawing or pulling feeling in the face, which, it will be observed, is quite like the description of the pain in true trigeminal neuralgia. Less frequently the distress is described as gnawing, sore, toothache, knifelike, pricking, beating, needle-like, gripping, bugs-creeping, electric, tingling, lightning,

bursting, nagging, stinging, smarting, itching or tearing. These sensations persist for minutes, hours, or on occasions are present to a certain degree constantly for days. They are aggravated by cold, fatigue, heat, draught, menses, excitement, eating, brushing teeth, talking, worry and other irritating factors.

It will be noticed that the most frequent factor aggravating the pain is cold, which also initiates the paroxysms of trigeminal neuralgia. It is therefore not surprising that the atypical and typical trigeminal neuralgias may be confused at times, especially if a critical history is not taken. This is particularly apt to occur, for patients suffering atypical trigeminal neuralgias are quite susceptible to suggestion, and the inquiring physician stressing the symptoms of trigeminal neuralgia might easily induce them in such cases.

Not infrequently facial pain is associated with sympathetic phenomena, such as lacrimation, edema of the face, corneal and conjunctival injection, salivation, nasal discharge, flushing of the face, and nausea and vomiting. Somewhat more than half of the cases have such sympathetic phenomena associated with the pain. Rarely do the sympathetic phenomena occur without pain. The location of the pain does not necessarily predicate the sympathetic discharge. In other words, the patient may have pain in the lower jaw and lacrimation or conjunctival injection. In many cases the onset of the pain is referred to a specific incident, such as extraction of a tooth, a wound of the head, or some unusually intense emotional experience.

The location of the pain varies a great deal in these cases, and even in the individual case, but it differs from the typical trigeminal neuralgia in that it is never quite so localized or confined to one or two divisions of the trigeminal nerve. Usually it involves the side of the face, particularly the cheek and eyeball, and extends backward above and behind the ear into the side of the neck. It may, however, be more or less confined to the cheek, the eye, the cheek and eye, or occasionally to the lower jaw, but usually it radiates posteriorly in the direction of the ear and temporal region. In a few cases the pain is bilateral, extending across the midline to the opposite side of the face. The lips are most commonly said to be involved by such pain, the disturbance being felt in the perioral region on both sides and in the cheek and ear on one side.

In the majority of these cases, psychiatric examination reveals personality characteristics suggesting a psychoneurosis and the pain is often said to be psychogenic in origin. Why the neurotic manifestation takes the form of facial pain is not clear, and even a detailed analysis of the case is not always elucidative in this regard.

SYMPTOMATIC FACIAL PAIN

Many organic diseases of the head will give rise to facial neuralgia, some through the mechanism of referred pain but others due to direct irritation of the trigeminal nerve. Among the more common conditions causing pain in the face are sinus infection, dental abnormalities, ocular disorders, neoplastic disease and vascular disturbances.

Sinus Infection as a Cause of Facial Pain—The pain resulting from infection of the air sinuses is usually dull and aching in character. Rarely are there acute paroxysms such as one encounters in true trigeminal neuralgia. Not infrequently the pain is aggravated in the afternoon as the sinuses become filled with mucus. The history of a previous cold and the presence of a nasal discharge and local tenderness over the sinus aid in the diagnosis. Poor transillumination and roentgenologic evidence of clouding usually confirm the diagnosis. The paroxysmal pain of trigeminal neuralgia is rarely, if ever, an accompaniment of sinus infection.

Dental Abnormalities—Without question the teeth are considered by the laity to be the usual cause of facial pain and yet actually they are rarely the responsible agent. Dental caries, gingivitis and apical abscesses do give rise to facial pain, which may be limited to the diseased tooth or referred to a division of the trigeminal nerve. Usually the discomfort is a persistent ache accompanied by local soreness aggravated by biting or eating. Impacted wisdom teeth may produce a chronic ache in the side of the face but rarely do they give rise to a typical trigeminal neuralgia. The ache is usually referred to the region of the ear and may be aggravated by chewing or movements of the jaw. Malocclusion of the teeth associated with temporomandibular arthritis does induce a severe pain in the side of the face, which occasionally has sharp agonizing exacerbations. This syndrome, like those previously mentioned, usually consists of a persistent pain that is present most of the time, aggravated by eating, chewing and movements of the jaw. Upon examination there may be an audible creaking of the joint on auscultation and tenderness on pressure. Dental appliances to relieve tension upon the articulation usually suffice to alleviate the discomfort.

The following case illustrates a rare dental complication.

I L., a 36 year old housewife, was admitted to the University of Chicago Clinics April 7, 1943, complaining of severe pain in the left mandible. In 1939 she had a block of the inferior alveolar nerve for removal of an impacted wisdom tooth, following which the lower jaw remained numb and the face became painful. The numbness persisted, but the pain varied considerably in intensity. About two y

before admission the pain became severe again and was not relieved by local dental procedures. The pain continued and about a month before admission an alcohol injection was made in the lower jaw. This therapy, however, aggravated the pain. It was described as a constant ache with sharp stabbing exacerbations radiating into the temple. In general the pain centered about the lower jaw but it was present in the cheek and the temporomandibular articulation with radiation to the left ear. Codeine was necessary for relief.

Her past and family history revealed nothing relevant to the present complaint except that she had had many previous illnesses, dysmenorrhea, nervous exhaustion, heart "strain," and recurrent periods of depression initiated by strenuous emotional situations.

Physical and neurologic examinations were quite normal except for the findings referable to the left side of the face and jaw. Over the distribution of the third division of the left trigeminal nerve a hypesthesia to pinprick and cotton was present, but deep pressure in this region was painful. The remaining teeth were in good repair but there was a scarred area in the posterior portion of the left lower alveolar arch, at the site of the removed wisdom tooth, which was tender to touch or pressure. Any manipulation of this area caused severe pain.

The patient was seen by dental surgeons, who found no dental abnormalities but considered the scarred alveolar ridge an adequate source of her trouble. The mandibular nerve was blocked by novocaine, with complete relief of pain and abolition of the sensitivity of the scar. She was then able to bite well, a process that formerly was quite painful.

Roentgenograms of the temporomandibular joint showed no abnormality. Occlusion was adequate.

Section of the lower divisions of the left trigeminal nerve was advised, but the patient wished to consider it since she was apprehensive of the operation and its sequelae.

On June 6, 1943, she returned because the pain was increasing and she was forced to take 3 grains of codeine daily for relief. Her clinical findings had not changed in the interim.

On June 8, 1943, the patient was anesthetized by intravenous sodium pentothal. A vertical incision was made in the left temporal region and carried through the temporal fascia and muscle. The bone was perforated, and the opening enlarged by rongeurs. The dura mater was elevated from the floor of the middle fossa, until the foramen spinosum was identified. It was plugged by a small piece of cottonoid and the middle meningeal artery was cut. The dura mater was then separated from the sheath of the third division of the trigeminal nerve. An incision was made in the sheath posterior to the gasserian ganglion and the sensory roots of the third division were avulsed. A few fibers of the second division were removed but the motor root, readily identified, was left intact. Moderate oozing was controlled by muscle

stamps The muscle, fascia and skin were then closed in anatomical layers by interrupted black silk sutures

The patient had an uneventful convalescence and was completely relieved of pain The alveolar margin was no longer tender and painful The area innervated by the third division of the trigeminal nerve was completely anesthetic as well as the greater part of that supplied by the second division The left masseter muscle contracted feebly The patient was discharged from hospital on the fifth postoperative day

She has been seen on two subsequent occasions, the latest one February 23, 1944 At that time she had no pain in the face or jaw, but a pressure sensation about the left ear She had been worrying a great deal and suffered headaches and insomnia There was still an anesthesia of the area supplied by the third division of the left trigeminal nerve and marked hypalgesia of the second division The masseters both contracted strongly She was well satisfied with the result of the operation

Vascular Disturbances—Another type of facial pain that occasionally tends to be confused with trigeminal neuralgia is the so-called *histamine headache*, which is presumed to be due to vascular disturbances¹⁰ The attacks occur usually at night or in the evening with a peculiar regularity and are associated with profound flushing and lacrimation on the affected side Night after night the patient may be awakened at the same hour by a severe, throbbing, unilateral pain in the temple, cheek or eye The attack has a sudden violent onset, lasts thirty to sixty minutes, rarely longer, and subsides rapidly The carotid vessels may be tender during the episode. There is no associated vomiting or visual hallucinations, and the affected patients rarely have a migrainous history Alcohol may precipitate an attack and the subcutaneous injection of histamine regularly induces it. In some cases so-called "desensitization" by repeated small doses of histamine will relieve the attacks. The syndrome in its pure form is so typical that it is readily recognized

Another type of probable vascular disturbance occurs in individuals subject to migraine, who will have attacks of severe pain in one side of the face lasting for hours and gradually disappearing The more gradual onset, longer duration of the attack and previous history of migraine serve to differentiate this condition from histamine headache and to indicate its nature

Bony Involvement as a Cause of Facial Pain—Occasionally small lesions of the frontal or temporal bone may be responsible for facial pain Thus osteomyelitis of the skull, luetic osteitis and epidermoid tumors may be the cause of localized head pain Usually the cause of

the trouble is recognized by roentgenographic examination of the skull. At times local tenderness over the area may be present.

Ocular Origin of Facial Pain—The discomfort produced by refractive errors is usually spoken of as a frontal headache, rather than as a pain. Its relationship to eye-strain is usually quite evident—although occasionally bouts of pain may occur apparently independent of the use of the eyes. Iritis and glaucoma may be associated with intense referred pain in the cheek and temple as well as the orbit, but the associated visual disturbance and ophthalmologic findings are usually sufficient to enable an accurate diagnosis.

Intracranial Causes of Facial Pain—Any lesion of the posterior root, gasserian ganglion or peripheral branch of the trigeminal nerve may give rise to facial pain. If the disease is peripheral to the posterior root the pain is usually of a constant character and may be referred to one or all of the divisions of the trigeminal nerve. Lesions along the root and pons are apt to induce paroxysmal pain as described under symptomatic trigeminal neuralgia. The condition may be differentiated from local disease in the face by the presence of sensory disturbances and subjective paresthesias.

Tumors of the gasserian ganglion early give rise to severe pain and numbness in the face.¹³ The pain may be paroxysmal but some residual discomfort is usually present between attacks. These tumors are usually carcinoma extending from the nasopharynx but occasionally primary neurofibromas, meningiomas or epidermoids may be found.²¹ Rarely a temporal lobe glioma will compress the gasserian ganglion producing pain.

Herpes zoster of the gasserian ganglion is not infrequent and may involve any one of the three branches of the trigeminal nerve. The history of such cases is usually typical. Severe pain and redness is present in one or all divisions of the trigeminal nerve, followed in two or three days by a vesicular eruption on the face. The vesicles gradually dry leaving a brownish scale. The pain usually recedes at about the same time but for several weeks the involved area may be hyperesthetic to the touch. Paroxysmal or persistent pain may continue for months. X-ray therapy will sometimes give relief for this type of pain. Retrogasserian neurotomy usually does not stop the pain although in a few cases relief is obtained. A Sjoqvist medullary tractotomy has been performed with fair results in one case.²⁷

Occasionally one sees uni- or bi-lateral trigeminal neuritis as a manifestation of a generalized peripheral neuritis in the *Guillain-Barré syndrome*. The diagnosis is obvious, due to the accompanying manifestations of peripheral neuritis. A neuritis of one or both trigeminal nerves

occurs, presenting the clinical picture of facial pain, tenderness of the peripheral nerves especially at the supraorbital, infraorbital and mental foramina numbness of the face and impaired sensibility in the distribution of the trigeminal nerve. The etiology is usually indeterminate but occasionally a toxic agent such as trichlorethylene may be incriminated.

Along their course from the gasserian ganglion to their foramina of exit upon the face the branches of the trigeminal nerve may be involved by inflammatory, traumatic or neoplastic processes. Comment should be made of the fact that *intracranial aneurysms* may be responsible for facial pain. These vascular anomalies usually involve the trigeminal root between the gasserian ganglion and pons, at the gasserian ganglion or more commonly the ophthalmic division of the trigeminal nerve as it passes along the cavernous sinus. The history and neurologic findings are usually sufficient for the diagnosis.

NEOPLASIA AS A CAUSE OF FACIAL PAIN

Unfortunately, new growths of the nasopharynx, sinuses, tongue and neck may invade so extensively before their presence is suspected that surgical intervention is not feasible. These tumors, in spite of radium or roentgen ray therapy, frequently cause severe aching pains in the face, which require large doses of opiates for relief. The diagnosis is usually obvious, but occasionally an early case presents difficulties until the nasopharynx is carefully examined. Roentgenograms revealing erosion of the base of the skull or a mass in the sinus are valuable diagnostic aids. Once the diagnosis has been established by biopsy, even if local surgical intervention is contemplated for the relief of pain, nerve section or injection should be considered.

The patient, having been made comfortable, will probably regain his appetite, put on weight and improve his general condition and morale so that a more radical attack may be made upon the tumor. X-ray therapy rarely relieves the pain, in fact in some cases the distress is precipitated or aggravated by such therapy. Too often neurosurgical intervention is thought of as a last resort to be employed only when all else has been tried and found wanting. But the patient, exhausted by his agonies and depressed by the failure of all medical therapies, is so weak in body and spirit that adequate neurosurgical methods are inadvisable. Both Munro²⁸ and Grant and Weinberger¹¹ have clearly shown the value of early surgical palliation in malignant disease of the face.

If the pain is confined to the face, alcohol injection of the gasserian ganglion may be sufficient to give relief. However owing to the

invasion of the base of the skull by tumor tissue, such an injection is often difficult and hazardous. For that reason retrogasserian neurectomy should be considered. If this means of relief has been too long delayed and the patient is riddled with metastases in the cervical nodes, a more extensive procedure must be carried out, with section of the trigeminal nerve and the ninth cranial and upper cervical posterior roots on the affected side. This procedure is a formidable one, under such circumstances carrying a fairly high mortality, nevertheless, it is one which is gratifying to the patient. At times this procedure cannot be carried out due to technical difficulties or tumor invasion, in which event mesencephalic tractotomy²⁸ may give relief, as in the following case.

H. M., a 28 year old accountant, was admitted to the University of Chicago Clinics on April 19, 1944, to the service of Dr. Walter Palmer with the complaint of pain in the left side of the face for one year, inability to open mouth, one year, swelling in the left side of the roof of the mouth, two months, and weight loss of 25 pounds in six months. Five or six years before admission he developed a postnasal drip for which a submucous resection was performed. Some relief was obtained but the discharge continued. In the spring of 1942 he noticed a lump under the left jaw which increased to such a size as to cause difficulty in swallowing. The mass was removed and reported to be Hodgkin's disease.

Early in 1943 a roaring sound was noted in the left ear. At the same time the left jaw began to ache and could not be opened as widely as usual. The pain gradually increased in severity. X-ray therapy (3400 r) was given to the left side of the neck with some temporary relief of the pain. In November 1943 cobra venom was used for the relief of the pain with little success. In December 1943 the patient began to have fever in the afternoon as high as 101° F. associated with general malaise. Since February 1944 he had nosebleeds every week. The pain in the jaw and neck increased. His jaw could be opened only sufficiently to take liquids. The left side of the throat became sore. The pain was so intense that aspirin, codeine and dilantin were used for its relief.

His past history yielded no significant data.

The patient was a well nourished and well developed adult. His thorax, abdomen and extremities presented no abnormalities to clinical examination. There was a 6 cm. scar in the left anterior cervical triangle. The hair was epilated from the left temporal region. The jaw could be opened only 1 to 2 cm., flexion and rotation of the neck were limited although extension was full. A few shotty lymph nodes were palpable in the submaxillary region.

On neurologic examination a small area of hypesthesia was found

anterior and below the left ear Weber's test was localized to the left ear No other sensory abnormality was found

On nasopharyngoscopy a rounded mass was seen covering the opening of the left eustachian tube This mass was biopsied and reported to be carcinoma

In view of the poor prognosis and relatively little relief from x-ray therapy a retrogasserian neurotomy with section of the ninth cranial and upper cervical roots was suggested On May 2, 1944, the patient was anesthetized with 100 mg/kg of avertin per rectum Upon placing him in the cerebellar head rest it was found that his head could be flexed only slightly and that with embarrassment of respiration For this reason it seemed advisable to abandon the original plan and do a mesencephalic section of the pain fibers for which flexion of the head was unnecessary A small temporo-occipital bone flap was made, four perforations being used The bone was fractured at the lateral sinus The dura mater was incised and a flap turned down The cerebral veins passing into the lateral sinus were coagulated and cut The occipital lobe was then elevated exposing the tentorium which was incised to the incisura The arachnoid over the lateral surfaces of the mesencephalon was gently teased away The trochlear nerve, superior cerebellar arteries superior colliculus and lateral sulcus of the mesencephalon were identified Across the brachium of the inferior colliculus ran two vessels one of which appeared to be an artery An incision 5 mm deep was made from the lateral sulcus to just below the superior colliculus, but it was broken at the artery The occipital lobe was then allowed to fall back into place, the dura mater was closed the bone flap replaced and the scalp closed with two layers of black silk

The patient developed a transient hyperthermia to 104° F within ten hours of operation He suffered no pain in the left side of the face and neck but was quite drowsy For four days he had periods of irrationality

Six days after operation the patient was examined in detail His left pupil was 5 mm, the right 4 mm but the reactions were brisk External ocular movements were full He had a homonymous constriction of the visual fields on the left side The entire left side of the body was hypalgæsic and the left side of the face and neck analgesic (Fig 25)

He was discharged on May 13 at which time he walked slowly and unsteadily His speech was slow and slurred He still had a left homonymous incomplete hemianopsia External ocular movements were full The left pupil was still larger than the right He was unable to distinguish the head from the point of the pin on the left side of the face and neck The corneal reflex was active bilaterally Finger-to-nose test was unsteady terminally on both sides The extremities were slightly weak but about the same on the two sides The tendon re-

flexes were active and equal, the plantar reflexes were flexor. Except for the left side of the face and neck, pinprick appeared to be well appreciated over the extremities and body. Below the left knee, hot and cold sensations could not be distinguished.

On May 30 his father wrote "He does not suffer any pain, and his mind is clearing noticeably, but he cannot speak clearly, and the numbness in his left arm and leg still annoys him."

Fig. 25—Photograph of the patient (H. M.) showing the degree of analgesia of the left side of the face ten days after mesencephalic tractotomy for a nasopharyngeal malignancy.

A month later the father wrote that the patient was developing a right hemiparesis and had a large mass on the right side of the neck. It seems obvious that much of his speech difficulties and mental confusion were probably the result of cerebral metastases, present but unrecognized at the time of the operation.

This case illustrates the difficulties in the surgical treatment of intractable facial pain due to neoplasia. In spite of a satisfactory surgical result, the tumor had advanced so far that the full benefits of the operation were not realized. Had operation been done a year

earlier the patient would probably have been spared much suffering by a simpler procedure

GENERAL CONSIDERATIONS OF FACIAL PAIN

It has become obvious from this discussion that an accurate description of the facial pain is essential to a clinical diagnosis. Not only the type of pain but its location, modes of initiation and methods of relief are important considerations. A complete physical examination with careful attention to the head is the next desideratum. Although the neurologic examination will frequently elicit no abnormalities, it is important since the absence of sensory and motor disturbance in the face are prerequisite to a diagnosis of certain types of facial pain. Since the sinuses and eyes are frequent causes of facial pain, ophthalmologic and otolaryngologic examinations are essential. Finally, roentgenograms of the skull may confirm a clinical opinion or establish a diagnosis in puzzling cases. Through such a routine examination the basis of many facial pains may be determined. If a psychiatric examination does not elucidate the factors in the remainder, a policy of masterful inactivity while time weaves the tangled threads into a comprehensible pattern, will pay satisfactory dividends both to the patient and physician.

The treatment should be directed towards removal of the causative factors whenever possible. For those cases of *typical trigeminal neuralgia*, retrogasserian neurotomy still remains the best operative treatment. As Grant emphasizes *tic douloureux* does not kill. The treatment must then be as safe and sure as possible. Although operations on the brain stem have distinct theoretical advantages, practically the technical difficulties encountered and the uncertainty of the procedures outweigh the possible gain in the average case. Whether the retrogasserian neurotomy is performed by the subtemporal or suboccipital approach seems to be a matter of the operator's preference and experience. In the hands of most neurosurgeons the subtemporal approach would appear to be the safer of the two.

The surgical treatment of *intractable pain in the face due to malignancy* should be undertaken early so that adequate operative procedures may be performed. If the pain is limited to the face a retrogasserian neurotomy should be sufficient. If the pain extends to the neck a more extensive denervation is necessary. A medullary tractotomy with section of the glossopharyngeal nerve and upper cervical posterior roots would seem to be the simplest method of obtaining relief. Mesencephalic tractotomy may, however, prove to be a less formidable and equally effective procedure.

For those cases of *atypical trigeminal neuralgia*, not relieved by diagnostic novocaine or alcohol block of the Gasserian ganglion, neotomy is not indicated. Section of the trigeminal nerve in such cases will usually aggravate rather than relieve the condition. If psychiatric therapy is ineffective, psychosurgery may perhaps be tried. Only time can tell what relief, if any, may be expected from prefrontal lobotomy.

CHORDOTOMY FOR INTRACTABLE PAIN

ADRIEN H. VERBRUGGHEN, M B, CH M, M S *

INTRACTABLE pain is a problem which has faced the general practitioner for many years and it is likely to continue to do so for a good many more. Scarcely anyone who practices medicine escapes without having had at least a few bitter experiences with patients slowly dying of an incurable disease in which pain is the major problem to which the physician must direct his attention. In many cases the duration of the pain is fortunately short but in others it is long and lingering, and the slow downhill progress of the patient is marked by the most terrifying pain.

Until the beginning of the century the practitioner relied on drugs as a rule to control the pain. The most useful were usually derivatives of morphine. In about 1905 Spiller and Frazier perfected the operation of chordotomy, which simply means the interruption of pain pathways in the spinal cord. Any incision into the cord is called a chordotomy (or cordotomy), but the word is now used to indicate the cutting only of the pain and temperature fibers. When it could be properly applied, in many cases it has been of great help, however, as will be seen as the discussion continues, it has a somewhat limited sphere of usefulness. The procedure is not familiar to the general practitioner nor are its advantages, or recourse would be made to it much more often than it is. It is of value in a variety of conditions such as the gastric crises of tabes, the intractable pain of malignant disease, the intractable pain of amputation stump neuralgia and the intractable pain of phantom limbs. It is for the intractable pain in malignant disease, however, that the operation finds its most frequent application. The anatomy of the part will first be described and later the particular kind of case to which the operation is applicable.

ANATOMICAL CONSIDERATIONS

The pain fibers of the lower extremities, and for that matter of the trunk and upper extremities also, are gathered together in a bottleneck in the spinothalamic tract. The fibers enter the spinal cord by the posterior roots and cross over to the opposite side, however, they

* Associate Clinical Professor of Neurosurgery (Rush), University of Illinois College of Medicine, Neurosurgeon, Presbyterian, Cook County and Michael Reese Hospitals

may travel up the cord on the same side and cross at various segmental levels up to six segments above the point of entry. To be sure that the pain will cease at any given point it is necessary to cut the spinothalamic tract at least six segments above that intended to be freed from pain. When the pain fiber crosses it does so as a new relay and passes close to the central canal into the spinothalamic tract of the opposite side. The fibers then travel up the spinal cord to the thalamus. (See Fig. 26.)

Fig. 26—Simplified diagram of the course of the pain and temperature fibers.

All of the fibers that enter the spinothalamic tract lie deep in the cord at first and later approach the surface. Those that enter the lower tract are more superficially situated than those that enter higher up. So the most superficial incision into the spinothalamic tract would produce anesthesia at the lowest segmental level—that is about the anus and perineum. As the incision is deepened into the spinothalamic tract the leg on the opposite side would become free from pain and temperature sense at a higher and higher level. Finally, if the incision is still further deepened the structures segmentally still closer to the

wound would be deprived of their pain and temperature fibers. In other words, the segmental level of anesthesia is raised by deepening the incision into the spinothalamic tracts. These tracts are situated on the anterolateral aspect of the spinal cord almost immediately anterior to the *dentate ligaments* (Fig. 27). The dentate ligaments are folds of pia mater which support the spinal cord and attach it to the dura mater between the exits of spinal nerves. The dentate ligament is an important landmark in the actual operative procedure. Somewhat pos-

Fig. 27—Transverse section of the spinal cord demonstrating the dentate ligament and the spinothalamic tract

teriorly and at a slightly deeper level run the *pyramidal tracts* and the *rubrospinal tracts*. These two are the main hazards in performing the operation. Naturally, section or even partial section of the pyramidal tracts would result in weakness of the legs, and this is to be avoided. At the same time an insufficiently deep incision into the spinothalamic tract would mean that the level of anesthesia might perhaps not be high enough to include all the painful area.

The incision is actually made about a millimeter anterior to the

dentate ligament and is of a depth of 3 mm into the cord. It is made transversely and the knife is withdrawn at a point corresponding to the line of exit of the anterior nerve roots. If the pain is strictly unilateral, it may be possible to perform a unilateral chordotomy, but as a rule it is necessary to perform chordotomy on both sides.

As a rule chordotomy is performed for intractable pain below the sixth thoracic segments. A high cervical chordotomy around the second cervical segment for patients with intractable pain as high as the

Fig 28.—Extent of analgesia following chordotomy of the second thoracic segment.

shoulder has been reported, but the operative procedure is somewhat more hazardous and the selection of cases much more difficult than for the routine procedure that is being discussed. What is said here has to do only with high thoracic chordotomy, certainly no higher than the first or second thoracic segments. With a properly conducted chordotomy at the second thoracic vertebra it ought to be possible to produce anesthesia up to the xiphoid process with interruption of the pain fibers below that level (Fig 28). This is not quite high enough to relieve all cases with the gastric crises of tabes, but for the

most intractable diseases of the lower abdomen and pelvis, such as carcinoma of the rectum, carcinoma of the prostate, and other similar conditions, the incision is quite high enough

As previously stated, the operation is nearly always bilateral. The patient with an inoperable carcinoma of the uterus may have extremely severe pains down one leg and possibly some minor pains down the other leg. The latter may become much more noticeable after the more severe pain has been relieved. Unilateral chordotomy is only done in a strictly unilateral disease and where the disease is likely to remain unilateral.

COMPLICATIONS

It is to be understood, of course, that only pain and temperature fibers are disturbed in this operation, and in such a way as to interfere very little with the rest of the structure of the spinal cord. All the disabilities and dangers and complications of the operation can be foreseen by considering the technic of the operative procedure.

Retention of Urine—One of the common disabilities is retention of urine. This is a very sensitive mechanism, especially when there has been interference with the spinal cord. In the days when the chordotomy was done on both sides at the same segmental level and with the two incisions tending to approach one another, there may have been some edema of the cord. This may have led to temporary retention of urine. Some of this can be avoided by staggering the incisions, that is, the incision into the spinothalamic tract is made at a certain level on one side and at a higher or lower level on the other. Even then, however, when incisions are made rather too deep and into the grey matter of the cord, temporary retention of urine may result. As a rule, with suitable care the retention clears up in two or three weeks. The usual procedure is to place an indwelling catheter in the bladder and to give urinary antiseptics. After a week or two the catheter may be clamped off for a few hours to determine whether the patient has any sensation of fullness of the bladder. Under ordinary circumstances, voiding soon becomes normal. In a previously healthy spinal cord and a previously healthy bladder, I have not seen a case of urinary retention and urinary difficulty which continued for more than a month. There may be also some loss of sexual function which, of course, is much more conspicuous in the male. Erection is possible, but orgasm is lost. Orgasm is also lost in the female.

Weakness of Legs—An incision which was rather too deep may nick or cause some disturbance of the adjacent pyramidal tracts, and in that case weakness of the legs will develop immediately after operation and may persist two or three weeks and even longer. I have not

seen a case of permanent paraplegia in an otherwise healthy cord, in which the chordotomy was the primary cause of the condition. Most patients on whom a chordotomy is to be performed are usually weak in the first place and their restricted activities are such that some weakness in the legs is not particularly noticeable. Most patients would be willing to sacrifice some strength in their legs to be free from pain for the rest of their lives.

Mortality Rate—The mortality rate of the operation is of no practical consideration whatever as most of the individuals for whom the operation is suggested are going to have a very short span of life in any case. The object of this is merely to make that life, such as it is and as long as it lasts, as happy as possible. Simple laminectomy in healthy individuals would give a mortality of less than 1 per cent. If the operation is performed in an otherwise healthy person with, say, an amputation stump neuralgia or the gastric crises of tabes, the mortality rate is extremely low. Exception must be made for morphine addicts. The mortality rate in the person who is dying of malignant disease and has intractable pain may be considerably higher. Furthermore, the question of the mortality rate is really that of the disease for which the chordotomy is performed. The more seriously ill the patient and the more run-down his general condition, the higher is the mortality rate.

INDICATIONS FOR AND CONTRAINDICATIONS TO CHORDOTOMY

The *indications* for chordotomy may be said to consist of (1) intractable pain below the costal margin that cannot be successfully controlled by medication and (2) the possibility of the patient's living a few months in a satisfactory general condition.

Naturally, it is important to try to control the pain first by local means and later by general means. If diseased and irritating tissue cannot be removed, general medication must be used, first with non-narcotic drugs and finally with narcotics. It should be estimated that the patient has a few months to live to make the discomfort and the risk of the operation worth his while. It goes without saying that in a very ill debilitated patient, the possibility of doing a major operation, no matter how simple it may be in a healthy person, carries with it a grave risk. Some individuals are at the end of their physical and mental strength and any major procedure could not be contemplated.

The *contraindications* are (1) a short life expectancy, say a month or six weeks, (2) poor general condition, and (3) morphine addiction (possibly). The first two are self-explanatory but the third requires a little discussion. *Morphine addiction* is quite common in those with

intractable pain The use of the word addiction perhaps should be limited to those in whom the taking of morphine, and not the relief of pain, is the primary concern It is very hard to distinguish, on occasion, the one from the other The morphine addict who has gastric crises is very difficult to relieve of pain The desire for the drug prevents the patient from admitting that he has no pain Patients should be offered a chordotomy rather early in a disease which obviously will result in a choice between this and large doses of narcotics If the large doses of narcotics are first used, chordotomy may not be satisfactory In those who have had large doses of morphine before operation, it should not suddenly be withdrawn afterward, as this produces the curious symptoms of restlessness and emotional instability with anorexia which may complicate the picture It is, of course, impossible to treat a patient with intractable pain for very long without giving him morphine, but still it should never be given in large doses, say half a grain every three or four hours for a period of several weeks, before the thought of chordotomy, as an alternative, enters one's mind

SELECTION OF CASES

The selection of cases for chordotomy is difficult because pain is such a subjective matter Some people seem to bear pain very well, and in others the slightest pain makes them acutely uncomfortable The practitioner who attends the case usually has a good idea as to how much pain there is and how difficult it is to control However, in selecting patients for chordotomy it is important to know more than this, principally because there are occasionally untoward results which may require explanation These have been mentioned namely, weakness in the legs and retention of urine It is true that these are transitory, but still in patients who have very little pain and who substitute weakness and temporary bladder disturbance for their slight pain, there may be criticism of the management of the case

A useful way of selecting cases is to explain to the patient the type of operation and to magnify the risk involved, for instance, to quote a 10 or 15 per cent risk of life and mention the possibilities of weakness of the legs and transitory bladder disturbance The patient who has a great deal of pain, and to whom that pain is intolerable, does not stop to argue about possible weakness in the legs and possible transitory bladder disturbance, his only concern is immediate relief from the pain Such a patient may say, "Can you operate on me today?" On the other hand, those whose pain is not very severe, judged by this standard, are inclined to ask questions of a rather superficial nature about exactly where the operation is to be per-

formed, the type of incision to be used, the number of laminae to be removed and even if they will be uncomfortable after the operation.

"Will I have to lie in bed for one week or two weeks," and "What about the possible danger of weakness of the legs?" may be asked. I have invariably refused to perform chordotomy on this type of person and, furthermore, I have rarely seen such a patient get into the proper state of mind for a chordotomy later in his illness.

It is always wise to take other members of the family completely into one's confidence. But here again, it is quite possible that some young, robust individual will say that he doesn't wish his mother to be further interfered with and will not allow the operation to be performed, whereas the patient, who may be in perfect control of her senses, is extremely anxious to have it done. When situations such as these arise, it is important to point out to all concerned that this operation is entirely for the relief of pain and will not in any way affect the outcome of the disease. It may be pointed out to the patient that after the operation the amount of morphine can be reduced and that he will be able to live free from pain. The fact that he has a malignant disease is probably not one which should be discussed with him, but with the other members of the family it is wise to mention this possibility, and to state that in all probability his life will be spent *relatively free from pain and with a clear mind*.

The process of keeping a patient under morphine for intractable pain for several months is an extremely tedious and tiresome one. The patient is apprehensive for fear some hitch will occur in the administration of the morphine and when he begins to get large doses he lives his life in a perfectly useless mental haze. With the operation an individual might make some use of the time that he has to live, a point which has not been sufficiently emphasized. Certainly there are still plenty of cases in which chordotomy cannot be properly applied and in which the only recourse will be repeated large doses of morphine.

TECHNIC

The technic of the operation is quite simple. We will assume that the pain is in the pelvis and is due to a carcinoma of the uterus with perhaps some scar tissue formation from radium treatment, that the pain of the lesion is uncontrollable and that the patient may live another six months. A rectal anesthetic such as avertin is given, if the patient can retain the anesthetic, and she falls asleep in her room. In the operating room an intratracheal tube is passed through which she is given nitrous oxide and oxygen. She is turned over flat on the operating table with her head on a head rest, especially designed for this

purpose, and the skin is marked to perform a laminectomy of the seventh cervical and first and second thoracic laminae. These laminae are removed. The bone is rongeué away more to the right at the lower end of the wound and more to the left at the top. This is done to expose the lateral part of the dura on opposite sides, because we intend to stagger our incisions, and put the right incision in the cord lower down and the left incision higher up. The dura is then opened between ligatures in a dry field and the cord is examined, the dentate ligament is identified, as it holds the cord to the sides of the spinal canal halfway between the exits of spinal nerves. This little dentate ligament is picked up on a mosquito forceps on one side and the cord is rotated so as to make visible its anterolateral surface.

A sharp No. 11 Bard-Parker knife, which is the type of knife with the long point and thin blade, is inserted a millimeter anterior to the dentate ligament and a cut is made forward toward the exit of the anterior root at a depth of not more than 3 millimeters. This depth is a matter of judgment. Some surgeons prefer to use a chordotomy hook which is inserted into the cord and a knife used to cut down upon it. Others use a knife which is guarded so that it cannot well be pushed into the cord for more than 3 millimeters. The procedure described is equally satisfactory. The dentate ligament above the one mentioned is picked up on the opposite side and an incision is made in exactly the same manner as that on the right. There is probably a distance of an inch to an inch and a half, or even two inches, between the two incisions measured in the long axis of the spinal cord. At a later date it will be noticed that the anesthesia is somewhat higher on the side of the higher incision than on the side of the lower incision. The dura is closed and the wound is closed in layers. The whole operation takes perhaps an hour or an hour and a half and it can be relatively bloodless.

Anesthesia—Many neurological surgeons feel that an operation of this type ought to be done under local anesthesia so that the segmental level of the anesthesia can be judged. During the operation the patient is tested with a pin and the incisions into the cord are deepened until the zone of anesthesia is well above the level of the pain. This may be very satisfactory in certain types of patients, but those who are really worn out with the pain cannot stand the hustle and bustle of an operative procedure such as this. The local anesthetic has to be very effective or they wear out and begin to cry. In others their condition is such that they do not pay sufficient attention to the examiner who is attempting, while the surgeon is operating, to estimate their level of anesthesia, so that their answers may not be very accurate. More-

over, in order to get it over with, so to speak, they may give definitely incorrect answers, as judged by responses later on when they have recovered from the operative procedure. It is purely a matter of choice and I prefer to operate, for the most part, under general anesthesia. There are certain conditions, however, in which it is wise to have the patients awake in order to estimate the level of the anesthesia before the wound is closed.

Postoperative Care—If the patient cannot void, an indwelling catheter is put in place and, of course, from hour to hour he is asked to move his legs, because after any laminectomy, it is possible to have bleeding in the wound and for the patient to lose power in the legs. As the days go on, however, the wound heals, the weakness in the legs is not apparent, at least while in bed, and the patient begins to feel bladder fullness as the catheter is clamped off and, finally, when he is allowed to sit up on the tenth or twelfth day he is able to void. At this point, if the urinary system is clear, the patient is turned over to the general practitioner who sent him, and from then on there is very little difficulty because of the absence of pain. Moreover, if such patients should require local treatment like douches or changing of packs or dressings of other kinds, these may now be done without pain. Before operation the dressings and manipulations may have been extremely painful in fact, so painful that they could not be properly done. From this point on it is possible to clean up local conditions and manipulate the part as much as is necessary to obtain proper local treatment. The patient, free from pain, is able to amuse himself, or perhaps he can work or do things that he finds it necessary to do. For instance, an individual may find it important to make arrangements for his family or to arrange to close his business. As far as the relatives are concerned, it is pleasing to them to be able to see and talk with the patient who otherwise would be merely an object of pity.

OTHER PAIN RELIEVING METHODS

There are, of course, other methods of relieving pain, especially in other systems which are not relevant to this discussion. We have not been concerned here with the relief of pain in the arm and breast, nor the relief of pain in the face and jaws. There are neurological surgeons who have performed satisfactory high chordotomies at the second cervical region. For malignant disease of the breast where the arm becomes painful and edematous some of these have been entirely satisfactory, others have not been so satisfactory and the mortality rate is sometimes unexpectedly high because death from respiratory failure is not uncommon. The pain in the arms and chest from malig-

nant disease of the breast is perhaps better controlled by posterior root section. Satisfactory results have been reported following this procedure. Pain in the face, mouth and jaws from carcinoma may be relieved by section of the sensory root of the fifth nerve, section of the ninth nerve or by an intramedullary tractotomy. Under certain circumstances these procedures may be combined and section of the sensory roots of the upper cervical nerves may be added to them. We of course have not discussed the pain of visceral disease such as the pain of interstitial cystitis or Hunner's ulcer. We have not discussed the pain of dysmenorrhea or angina pectoris, nor have we discussed causalgic pain. These belong in the class of sympathetic nerve pains which are usually relieved by direct attack on the sympathetic system. Chordotomies have to be at a considerable distance above the site of visceral pain in order to be satisfactory.

ILLUSTRATIVE CASES

CASE I—Mr. G. K., 39 years old, was admitted to the Presbyterian Hospital, Chicago, in October 1939, complaining of constant knife-like pain in the perineum. In February 1939 a bladder tumor, as well as his left kidney, had been removed. In August 1939 a further operation was performed on the bladder tumor. The tumors were said to be papillomas. The pain in the perineum had been present for a month before the second operation. In September 1939 the patient was having severe pain in the perineum but, as his bowels did not move properly, and because of the pain, his abdomen was opened and adhesions between the bowel and the bladder were reported to have been removed. The pain in the perineum was not abated. An epidural injection did not relieve him.

On October 14 an epidural injection of novocaine was given by me with instant relief. A few days later, with the patient in a suitable position, 1 cc. of absolute alcohol was injected between the fourth and fifth lumbar vertebrae. This was done very slowly. At first there was a burning sensation in the perineum, which disappeared in about one-half hour. (The pain disappeared with the injection.) The patient immediately had more trouble in emptying his bladder than he had before the injection. Next day an indwelling catheter was inserted. Six weeks after the injection, he was beginning to void without a catheter. Three months later he returned and the pain had reappeared in the perineum. He felt that the pain was so severe in this case that a chordotomy should be done.

A chordotomy was performed according to the routine procedure described in this paper and the patient remained free from pain until his death some five months later. For the first few days there was weakness in the legs and as soon as the operation was done it was

necessary to replace a catheter in the bladder. In this case it was possible to treat the patient before he had begun to rely too much on morphine and while he was in good condition. However, his bladder tumor finally caused his death at a later date but at least he spent the intervening five months in fairly good condition.

CASE II—A very similar case was that of another man, 52 years of age, with an inoperable malignancy of the prostate causing intractable pain. In every other way he seemed fairly normal. He walked into the hospital for relief of his pain, and readily submitted to bilateral chordotomy which was performed in 1932. Following the operation his legs were weak for a few days and his bladder gave him trouble and he had to have an indwelling catheter. In a month his legs had almost regained their normal power and he had little trouble with his bladder from that time until his death fourteen months later. He was extremely satisfied with the operative procedure.

CASE III—Mrs. D. B., 79 years of age, was seen by me in consultation with a practitioner in a neighboring hospital. For the last three months she had had a rapidly developing paraplegia from a carcinoma of the pelvis with metastases to the lumbar spine. She was having agonizing pain in the legs and in the lower abdomen. This pain would come on in spasms and caused the patient to break out in a cold sweat. She was extremely apprehensive of the next attack of pain and spent most of her time in the act of prayer. Although the condition of this patient seemed far from satisfactory, the acuteness of the pain was such that morphine was of little or no value to her. In spite of her age, a chordotomy was done with immediate relief of pain until her death six weeks later. Except for the extraordinary severity of the pain one would not perform an operation of this magnitude in a patient in this condition. However, for the six weeks after the operation she was able to converse with her grandchildren and other relatives and all in all these six weeks made the procedure seem worth while.

CASE IV—J. W., 49 years of age, first came to Cook County Hospital on January 10, 1940, with amputation stump neuralgia. He had had the right leg amputated below the knee as the result of an injury in 1931. In 1933 he had a reamputation with a short stump. Pain radiated down the back of the stump and he had had numerous injections and x-ray treatments. On January 17 the sciatic nerve was exposed and cut back about two inches from the scar without any further treatment. On April 8, 1940, he came in complaining of pain down the side of the leg and he stated that the pain down the back of the leg was not conspicuous at this time. In other words, the section of the sciatic nerve had relieved some pain. The lateral cutaneous nerve of

the thigh seemed to be involved on this occasion and was cut. On November 13, 1940, he was still having intractable pains rather unlocalized in his right leg and at this time it was suggested that a chordotomy be done. Chordotomy was done on November 20, 1940, on one side only with relief of pain. Apparently the relief has been maintained because the patient has been seen as late as January 1944 complaining of other things but not the amputation stump neuralgia. All amputation stump neuralgias do not respond to chordotomy. It has been suggested lately that possibly the way to deal with some of these is to ablate the sensory cortex corresponding to the leg.

CASE V—Mr. M. W., 60 years of age, was first seen at Cook County Hospital on February 21, 1939. He was complaining of acute abdominal pain radiating around both sides of the epigastrium. This had been present since 1932. In 1916 he had contracted syphilis and had been treated for it. Occasionally he vomited with pain, both pupils reacted fairly well to light and somewhat to accommodation. The ankle jerks and knee jerks were very feeble in both legs. The Wassermann reaction was negative on December 12, 1939. The history, especially that of the pain, made it certain that this was an example of the gastric crises of tabes and on January 10, 1940, a chordotomy was done. He was seen for several months, and one month after operation he stated that the sharp shooting pains had stopped, but he did have a dull ache. For some unknown reason he bled copiously from the bowel on two occasions. By May, five months later, he reported finally that he felt very much better and had only occasional slight twinges of pain above the zone of anesthesia produced by the chordotomy. On account of the lessening of the pain he was able to return to work and become a useful citizen and economically self supporting.

COMMENT

One may say in summary that this procedure is one which is too infrequently employed, partly because of lack of appreciation of the indications and the benefits to be derived, and partly because of reluctance to initiate new treatment or upset an established routine. The patient who has a diagnosis of incurable disease with intractable pain would have to be moved perhaps from a distance to a hospital where a neurological surgeon could perform the operation, and then he must be moved back. All of these things are drawbacks to taking the step toward chordotomy. In the majority of cases, however, where the operation is well thought out and properly indicated the result is very satisfactory, not only to the attending physician but to the relatives and especially to the patient.

PROTRUSION OF THE INTERVERTEBRAL DISK

HAROLD C. VORIS, M.D. *

PROTRUSION or herniation of the intervertebral disk has been known as a pathologic entity for a half century. Although its clinical significance escaped surgeons and neurologists for most of that period, the last ten years have seen an intense interest in the subject. Operation has been done in a large number of cases (Love and Walsh), and many articles and even monographs have appeared on the subject. It is now apparent that this lesion is much more frequent than was at first suspected, that it can often be recognized by careful clinical history and examination and that in properly selected cases surgical removal is the treatment of choice. These herniations may occur at any level of the spine but they predominate in the lumbar region and the great majority are from the fourth and fifth lumbar intervertebral disks. Recurrent pain of the so called root type is the usual complaint, only rarely does the patient present gross neurologic defects. Protrusions from disks above the first lumbar are the most apt to cause such gross neurologic defects by pressure on the spinal cord, simulating cord tumor. Even at these higher levels it has recently been recognized (Semmes and Murphy) that a small, lateral protrusion of the intervertebral disk may cause a syndrome of root pain with minimal objective neurologic findings comparable to the classic syndrome at the lumbar level.

Since over 90 per cent of disk protrusions are from the lumbar disks, and most of these from the fourth and fifth lumbar disks, this clinic will be confined to the problems arising in this group. Five cases illustrating certain important points will be presented in some detail with discussion of the individual problems of each case. Then a general discussion of various phases of diagnosis, treatment and results will complete the presentation.

CASE I—M D K, a physician 30 years of age, was referred by his brother, also a physician. Five years before while serving an internship he had had an attack of "lumbago" for two weeks. He recovered completely from this for fifteen months and then recurrence took place.

in the shape of mild "nagging" pain in the lower part of the back. This persisted with remissions and exacerbations. A sacroiliac belt had been of slight help. Treatment with an autogenous vaccine cultured from the nasopharynx had given considerable relief on another occasion. The patient suffered from chronic sinusitis and had noted a definite relationship between "flare-ups" of his sinus trouble and exacerbations of his low back pain. Both he and his brother had consequently considered his low back pain to be the result of absorption of toxins from his chronic sinusitis.

One month previously the patient had, for the first time, radiation of pain into the posterior aspect of the right thigh and leg. This pain was worse on coughing, sneezing or straining at stool. No history of definite injury was obtained, but the patient had always been robust and had done considerable heavy work at certain periods of his life.

General physical examination was essentially negative. Neurologic examination revealed diminution of the right ankle jerk and hypesthesia to pinprick on the lateral border of the right foot. The circumference of the right calf was 36 cm, the left 37 cm, the patient was right handed. An air myelogram was performed on March 9, 1940. With the head lowered to an angle of 35 degrees on the tilting table a spinal puncture was performed at the first lumbar interspace and 35 cc of spinal fluid were removed and air substituted. The total protein content of this fluid was elevated to 78 mg. Lateral and anteroposterior stereoscopic films revealed a defect in the right side of the air column opposite the lumbosacral interspace.

Operation on March 12, 1940 consisted of a right partial hemilaminectomy of the adjacent portions of the spines and laminae of the fifth lumbar and first sacral vertebrae. This together with resection of the ligamentum flavum exposed an area of dura about 2 by 1.5 cm. Retraction of the right fifth lumbar root exposed a large protrusion of the disk which had not ruptured completely through the posterior longitudinal spinal ligament. A cruciate incision was made in this structure and the fragments of disk material extruded and were readily removed. An unusual amount of fragmented cartilage was removed and a cavity 2 cm deep in the disk was produced. The dura was not opened and the wound was closed. Convalescence was uneventful and the patient left the hospital on March 29, 1940.

The patient returned to his office three weeks later but was cautioned against lifting or straining for a period of three months. Three months later he considered himself perfectly well. The right ankle jerk was still diminished and straight leg raising on the right still gave slight discomfort. The patient has remained well since, carrying on his practice without interruption. Recently he received a commission in the Medical Corps of the Army of the United States and has been ordered to active duty.

Comment—This case can be considered typical of the syndrome of unilateral protrusion of the fourth or fifth lumbar disk. After a considerable period of recurrent low back pain, unilateral sciatic radiation appeared. The sciatic pain was exacerbated by coughing, sneezing or straining. The ankle jerk was diminished on the affected side and there was definite hypesthesia about the foot on that side. Spinal fluid showed a mild increase in the total protein, and a contrast myelogram showed a definite filling defect of the spinal canal. Operative removal of the protrusion gave an entirely satisfactory result.

The exacerbation of the patient's low back pain with recurrence of his chronic sinus infection is of great interest. It shows that the presence of a known focus of infection and even a demonstrable clinical relationship between the focus of infection and the nerve pain in question does not prove the pain to be purely inflammatory or toxic. In this instance the irritated nerve root must have been a *locus minoris resistentiae* for toxins from the infected sinuses. A considerable number of patients have low back pain for months or years before the onset of nerve root pain. Roope has described the innervation of the annulus fibrosus and the posterior longitudinal ligament. In the early stages of disk protrusion this innervation is responsible for the patient's pain. Only when the protrusion is large enough or far enough laterally to impinge on the nerve root will the patient have radiating pain. Both the nerve root and the protrusion of the disk are slightly affected by postural changes and by muscle spasm. This accounts for the frequent exacerbations, often initiated by muscular strains, and the remissions afforded by bed rest, heat, diathermy and so forth. Many patients who are able and willing to limit their physical activity can avoid serious recurrences and live satisfactorily with their disk protrusion.

Spinal fluid examination and contrast myelography are not essential in the diagnosis of typical cases and were not here. The total protein content of the spinal fluid is often not elevated, and this finding while of great help when positive has no negative value. Contrast myelograms were thought at one time to be necessary in all cases. In fact it is doubtful if the intervertebral disk syndrome would have become well recognized without the aid of contrast myelography. Air and oxygen are the least desirable of the mediums in general use from a roentgenographic standpoint, but both have the advantage of rapid and complete absorption, leaving no trace of their presence and both produce little or no irritation. Lipiodol is far superior from a roentgenographic standpoint but is difficult to remove except at operation. In the writer's experience no irritative effects from lipiodol are

Fig 29 (Case I) —A, Preoperative roentgenogram, anteroposterior view B, Postoperative roentgenogram, anteroposterior view Note small amount of bone removal

Fig 30 (Case I) —A Preoperative roentgenogram, lateral view B, Postoperative (six months) roentgenogram, lateral view There is no change in the lumbo-sacral disk space which was narrowed before operation

clinically as a rule, rarely such effects are definitely produced. The new substance, pantopaque, is comparable to lipiodol from a roentgenographic standpoint and has the advantage of being readily removable by aspiration through a spinal needle. It is now becoming generally available.

This patient has had a good operative result over a four year period. The operative procedure consisted of simple removal of the protruded and fragmented portion of the disk through a limited but adequate operative exposure. As Fig. 29 shows bone removal was minimal. Although a large cavity was produced in the fifth lumbar disk, a lateral roentgenogram six months later compared with a preoperative roentgenogram (Fig. 30) showed no decrease in the intervertebral space. Spinal fusion was not done in this case although one of the so-called indications was present—that of low back pain for several years before the onset of sciatic pain.

CASE II—M. C., a punch press operator 45 years of age, had suffered from recurrent low back pain for the past twelve years. He had been treated more or less continuously as a case of spinal arthritis. Two weeks before admission he had begun to have pain radiating into the left lower extremity but was able to continue work until five days later when on arising in the morning he was paralyzed from the knees down. Since that time urinary retention and fecal incontinence had been present and the patient had been bedridden.

Neurological examination revealed weakness of the thigh muscles with paralysis of the calf and peroneal muscles. The right knee jerk was active, the left absent and both ankle jerks absent. Cutaneous sensation was lost over the posterior aspects of the buttocks and thighs (third to fifth sacral dermatomes) and impaired on the posterior aspects of the legs, over the feet and the anterior aspect of the lower third of both legs (fourth lumbar to second sacral dermatomes). There was an area of hyperesthesia to pinprick on the dorsum of each foot. Vibration sense was moderately impaired at the left ankle and slightly at the right. Position sense was impaired in the left toes.

A neurological consultant had performed a spinal puncture and injected lipiodol. He had not obtained fluid at the third or fourth lumbar interspaces but had obtained xanthochromic fluid that coagulated on standing at the fifth lumbar interspace. No rise in spinal manometric pressure had been noted on bilateral jugular compression. X-rays taken after his injection of lipiodol at that level showed all of the lipiodol below the lower part of the body of the fourth lumbar vertebra.

The preoperative diagnosis was tumor of the cauda equina opposite the third and fourth lumbar vertebrae. Operation was performed March 26, 1940 and consisted of laminectomy of the spines and laminae of the third, fourth and fifth lumbar vertebrae. When the lamina

of the fourth lumbar vertebra was removed on the left side, a tightly rolled extradural mass extruded itself and spontaneously unrolled. It proved to be a ragged piece of fibrocartilage 4 by 2.5 by 0.7 cm (Fig 31). Its inferior and anterior corner was still attached to the intervertebral disk between the fourth and fifth lumbar vertebra. It was readily removed. The ragged cavity in the intervertebral disk proved to contain no loose or fragmented cartilage. The dura was opened and the previously injected lipiodol was removed. The nerve roots were swollen and markedly injected.

Convalescence was uneventful. At the patient's dismissal from the hospital three weeks later bladder function had satisfactorily returned but the neurologic status was otherwise unchanged. Nine months later he was walking well with only moderately diminished strength and

Fig 31 (Case II) —Photograph of extruded portion of disk removed at operation

tone in the calf muscles. The left patellar reflex was diminished. Both ankle jerks were present but diminished. Sensation was still impaired in the third to fifth sacral dermatomes bilaterally. The patient claimed no difficulty with bladder function but admitted some difficulty in controlling the rectal sphincter. Four years later he reported good control of bladder and bowels, residual atrophy of the calf muscles, and complained only of easy fatigue in his lower extremities. He estimated his percentage of recovery at 90 per cent.

Comment —This was an extraordinary case. After years of low back pain, sudden and complete loss of neurologic function below the fourth lumbar roots developed, preceded by root pain of only a few days' duration. In the absence of a definite injury or strain it is diffi-

cult to explain the massive extrusion of the ruptured cartilage. Since then I have had a similar case. A 45 year old priest had had low back pain for ten years with recurrent sciatic radiation for a year. While in the hospital receiving conservative treatment he coughed at stool one morning and was seized with excruciating low back and bilateral loss of function below the third lumbar segment. A preoperative diagnosis of massive extrusion of intervertebral disk cartilage was made and verified at operation. The operative findings were similar to those of Case II except that the extrusion was one segment higher. A similar case was reported by Middleton and Teacher in 1911, and two others by Dandy in 1929. Recently French and Payne have reported eight cases of compression of the cauda equina due to disk protrusions. Such cases as this are rare but should be thought of in the event of sudden paraplegia, especially if the onset is associated with muscular strain or wrenching. If the extrusion is below the first lumbar disk *the prognosis for recovery is good, especially with early operation.* Such an accident above the first lumbar disk will usually result in permanent damage to the spinal cord. Localization is obvious from the neurologic findings, spinal puncture confirms the presence of a subarachnoid block, contrast myelography should not be necessary.

CASE III—M. N., a 40 year old mason, had injured himself in a fall twenty years before when he landed on his buttocks. Recurrent, low back pain had plagued him since and for the past four years there had been recurrent left sciatic radiation of the pain. This was exacerbated by coughing or sneezing and when sitting for any length of time numbness and tingling of the left lower extremity was noted. About a month before, right sciatic pain had appeared but was not as severe as on the left nor were there any paresthesias on the right side.

Examination revealed a markedly positive Lasègue (straight leg raising) sign on the left and a mildly positive one on the right. There was tenderness to palpation at the lumbosacral junction. Both ankle jerks were absent and there was hypesthesia to pinprick on the border of both feet. An air myelogram was carried out, 20 cc of spinal fluid being removed and air substituted. The total protein content of the fluid was 58 mg. The myelograms were not satisfactory. No air was seen below the fourth lumbar interspace.

Operation on September 22, 1942 consisted of partial laminectomy of the spines and laminae of the fourth and fifth lumbar and the first sacral vertebrae. The ligamentum flavum was resected at both the fourth and fifth lumbar interspaces. Part of the lamina of the fifth lumbar vertebra, a ridge of bone 15 mm wide, was preserved. The fifth lumbar and first sacral roots were markedly swollen but no evidence of disk protrusion at the lumbosacral level was found. At the

level of the fourth interspace there was a small protrusion on the left side near the midline. There was no rupture of the posterior longitudinal ligament. When the protrusion was incised, very little fragmented disk material escaped or could be removed. However, there was an extensive degeneration of the intervertebral disk as there was a cavity about 2 cm deep in the disk into which the aspirator tip or curet could be readily introduced. The dura was not opened and the wound was closed.

The immediate convalescence was uneventful and the patient was dismissed from the hospital on October 8, 1942. He was next seen on October 22, 1942 complaining of "a catch in his back" and bilateral radiation of pain into both thighs anteriorly. There was a marked list of the lumbar spine to the right and straight leg raising was painful, especially on the left. He was readmitted to the hospital and improved rapidly with inductotherm treatments, being dismissed again four days later. However, he continued to complain of low back pain and has not been able to work steadily. Spinal fusion has been advised but the patient has refused further surgery.

Comment—This case is an example of an unsatisfactory result. Spinal fusion was certainly indicated in this case and should have been done at the operation for removal of the disk protrusion. The evidence at operation of extensive disk degeneration without any marked protrusion suggests that the protrusion was of relatively little importance and the pathologic change within the disk of chief importance. This patient's attitude and personality made him a poor choice for surgical treatment. He was pessimistic before operation about the likelihood of relief and he had a low pain threshold with a tendency to exaggerate his complaints. For many years he had complained of a "weak stomach" with frequent gastric upsets, although repeated examinations by capable gastroenterologists had never revealed any organic cause for these disturbances. We would have done well not to have advised operation on this patient, if operated on he should have had a spinal fusion combined with removal of the disk protrusion.

CASE IV—J. N., a 35 year old grain broker, had had recurrent, low back pain for eight years, usually brought on by exercise and more frequent in the winter months. Extensive and prolonged orthopedic treatment had failed to give relief. For a week the pain had radiated down the posterior aspect of the right lower extremity and had been exacerbated by coughing or sneezing. The patient had been an active athlete in high school and college and had done heavy work during school vacations. He could not, however, give a history of a specific back strain or injury.

Examination revealed a moderately positive right Lasegue sign and definite lumbosacral tenderness. The right ankle jerk was diminished, there were no sensory changes. An air myelogram was carried out, 30 cc of spinal fluid being removed and air substituted. The total protein content of the spinal fluid was 67 mg. The myelograms showed a defect in the air column on the right at the fourth lumbar interspace.

Because of the minimal objective neurologic findings and the long history of low back pain, and with the case of M. N. in mind, further orthopedic consultation was advised. Dr. Perry Rogers saw the patient, concurred in the diagnosis of protrusion of an intervertebral disk and advised the combination of spinal fusion with removal of the

Fig. 37 (Case IV)—*A* Postoperative roentgenogram, anteroposterior view, six weeks after combined operation. *B*, Lateral view.

disk protrusion. The preoperative diagnosis was protrusion of the fourth intervertebral disk on the right.

Operation on February 2, 1943, consisted of exposure of the spines and laminae from the fourth lumbar to the second sacral vertebrae. The ligamentum flavum was widely resected at the fourth and fifth lumbar interspaces and a small portion of the adjacent laminae nibbled away. There was no evidence of disk protrusion at the fourth lumbar interspace. On the right, near the midline at the lumbosacral interspace, there was a large protrusion. The posterior longitudinal ligament was not ruptured but was so thin over the protrusion that it ruptured on gentle probing. A large amount of fragmented disk material was removed. The cavity in the disk after removal of the

fragmented material was 3 cm deep. Dr. Rogers then performed a Hibbs' type spinal fusion, using plaques of bone from the outer table of the right ilium, in addition to slabs of bone from the spinous processes, the laminae, and the posterior aspect of the sacrum.

Convalescence was uneventful. The patient was ambulatory in a body cast at the time of his dismissal on February 24, 1943. The cast was removed six weeks after operation. Figure 32 shows roentgenograms taken at that time. During the summer of 1943 he played tennis without ill effects. When last seen in May of 1944 he was perfectly well and was enjoying golf, badminton and tennis.

Comment—The result in this case is in marked contrast to that obtained in Case III with a comparable history. However, it would not be accurate to carry the comparison further. This patient was a much more stable individual—a very intelligent and highly successful business man who cooperated fully in his treatment. Moreover, he had a large protrusion of the disk which adequately accounted for his root pain. However, the very satisfactory result speaks well for the combined operation. It should be noted that the air myelogram not only failed to localize the lesion but was actually misleading, indicating a nonexistent protrusion at the fourth lumbar disk. Even at best air myelography is far inferior from a roentgenographic standpoint to lipiodol or pantopaque.

CASE V—D. M., a 27 year old housewife, had strained her back nine months before while carrying her baby upstairs in its carriage. Low back pain followed and within a few days became severe, and right sciatic radiation was noted with numbness of the right buttock and posterior aspect of the right thigh. The numbness had gradually improved but still persisted in considerable degree. She had been delivered of another child six months later but did not feel that her labor pains had been different from former labors or that labor had affected her low back or sciatic pain. The pain had been recurrent with every effort to resume normal activity.

Examination revealed a moderately positive Lasègue sign on the right and absence of the right ankle jerk. There was marked hypesthesia to pinprick in the right side of the perineum and the posterior aspect of the right thigh (third to fifth sacral dermatomes). An air myelogram was done, 40 cc of fluid were removed and air substituted. The total protein content of the spinal fluid was 50 mg per 100 cc. The myelograms showed a shift of the air column to the left opposite the fifth lumbar interspace. A diagnosis was made of a large disk protrusion on the right at the lumbosacral level. Neoplasm was considered a possibility because of the involvement of sacral dermatomes.

Operation on January 8, 1944 was a right hemilaminectomy of the fifth lumbar vertebra. Initially the ligamentum flavum was resected on the right at the fourth and fifth lumbar interspaces and the resultant opening then enlarged by nibbling away the adjacent laminae slightly with rongeurs. With this exposure no disk protrusion could be seen, but after complete removal of the right side of the lamina of the fifth lumbar vertebra a protrusion of the lumbosacral disk could be visualized near the midline projecting upward so that it could not be seen through the interlaminar space. The posterior longitudinal ligament was not ruptured, after its incision a considerable amount of fragmented cartilage and nucleus pulposus was removed. Extradural bleeding was troublesome and finally required several muscle pledgets to control.

Convalescence was uneventful and the patient left the hospital on January 24, 1944. The sensation in the right perineum, buttock and posterior thigh had improved, especially over the perineum and buttock. A month later no objective sensory disturbance could be found although subjective numbness of the posterior aspect of the right thigh was still present. The patient has not been seen since but reports by letter that she is entirely well.

Comment—This patient's sciatic radiation began within a few days of her low back pain. The onset was related to a definite back strain. Unusual features were the early paresthesias in the sacral dermatomes and the objective sensory disturbances in these dermatomes on examination. This protrusion near the midline was apparently large from the onset so that sciatic radiation of pain and sensory disturbances appeared very early. Some improvement had followed conservative treatment but she had been practically incapacitated from the time of her injury. She was six months' pregnant at the time of the onset but what role that played in the severity and persistence of her symptoms is difficult to assess. She noted no improvement after delivery. At operation this patient's disk protrusion could not be visualized through the usual interlaminar approach and complete hemilaminectomy of the fifth lumbar vertebra was necessary. Neurologic surgeons know that laminectomy, even if extensive, is not disabling nor does it weaken the spine if the articular facets are preserved. Other things being equal it is of course desirable to remove as little tissue and destroy normal relationships as little as possible in the removal of a disk protrusion. This desire should not lead to the failure to visualize the protrusions or adequately remove them through lack of exposure. The surgeon should not operate unless he is convinced that a disk protrusion is present, if he does operate, while his initial exposure may be limited

he should never fail to make an exposure adequate to visualize and remove the obstruction

GENERAL COMMENT

The History—The importance of a good history cannot be overestimated. Root pain, whether in the sciatic radiation or elsewhere, has certain rather constant characteristics. When present its location is constant, it is often worse at night, and it is usually exacerbated by coughing, sneezing or muscular straining. The past history must be carefully inquired into for attacks of back pain or sciatica in the past and for back injury or strain.

Examination—On examination the patient may limp on the affected side if the pain is severe. Often the lumbar spine lists away from the affected side, occasionally to that side. Localized tenderness at the affected interspace is a frequent finding. Straight leg raising is almost always painful, sometimes extremely so. The absence or impairment of the ankle jerk on the affected side or some degree of sensory disturbance in the affected dermatome or dermatomes is exceedingly important. In my own experience such objective neurologic findings were absent in only 15 per cent of the cases in which a disk protrusion was found at operation. On the other hand, in the cases in which I failed to find a disk protrusion, such objective neurologic findings were never present. It is obvious from this that, in the absence of objective neurologic findings, great care should be exercised in making a diagnosis of protruded disk. Probably contrast myelography should be used in all of these cases. It must be emphasized that the objective neurologic findings referred to are minimal and must be sought for carefully and skillfully. Bradford and Spurling, and Semmes have well emphasized the importance of careful neurologic examination.

Selection of Patients for Operation—The selection of patients for operation is very important. As has already been stated, many patients with mild symptoms can live fairly comfortably with their disk protrusion if they are brought through an occasional exacerbation of their symptoms by conservative treatment. This is particularly true of those individuals who are fortunate enough to be able and willing to avoid hard physical labor or strenuous exercise. Many patients with acute back strain have injury to the intervertebral disk and the annulus fibrosus or posterior longitudinal spinal ligament. However, with rest and perhaps temporary immobilization healing takes place and there is no recurrence of symptoms. Perhaps an improvement in the early management of low back injuries might lessen the incidence of later disk protrusions. In addition to those patients whose symptoms are not sufficiently marked to warrant surgical intervention, there is a group

of patients who do have severe and disabling complaints. However, these individuals, because of their personality and attitude (Case III) are likely to continue to complain after an apparently successful operative procedure or they may develop a new set of complaints after operation. All surgeons know this type of patient and learn to avoid elective operative procedures on him whenever possible.

Another group of patients with disk protrusions that is notoriously apt to obtain poor results from surgery consists of the compensation cases. Where it is feasible, the patient with a compensation problem should be encouraged to obtain a final settlement of his case and then seek relief from surgery. Such settlement should of course take into account his prospective medical and hospital expense. When surgery is carried out while the patient is still receiving compensation, the patient should be told frankly that after operation he will be expected gradually to resume full activity and finally return to work even at the expense of minor discomfort. Patients in this group with low pain thresholds, inadequate personalities, or who indicate resentment against their employer or the insurance carrier will seldom obtain a good result, at least during the period of compensation. The patient who has legal proceedings pending, either in court or before the Industrial Board, will seldom cease to complain until after these proceedings have been settled.

Patients who do require operation fall into three main groups. Those in the first group have relatively mild symptoms but circumstances or the patient's own desires (Case IV) demand considerable physical activity and the persistent recurrence of symptoms finally brings them to operation. If they can change their occupation or if they will give up strenuous exercise, an operation may be avoided. Many cannot do the former, some refuse the latter alternative. Selection of cases must be carried out carefully in this group.

A second group in spite of conservative treatment and limitation of activity continues to have recurrence of pain and also finally comes to operation (Case I). Patients in this group present fewer problems than the first group. Trial of conservative treatment has been adequate and the patient has been cooperative. The persistence of recurrences under such conditions warrants surgical intervention.

Finally there is a group of patients whose pain is constant and severe with any activity (Case V) or who develop marked objective neurologic disability (Case II). These patients present an absolute indication for operation because of their disability and suffering. Once the diagnosis is established, and in this group that is usually not difficult, surgery is indicated.

Surgical Management—The surgical removal of a disk protrusion, especially through a limited exposure, requires an accurate anatomical knowledge of the region involved plus certain special instruments and technic. The management of epidural bleeding is often troublesome, interfering with the exposure and removal of the lesion. If it is not controlled before the closure of the wound, postoperative hematoma with serious neurologic sequelae may occur. The use of suction and electrocoagulation is of great help. Small implants of muscle or, as recently suggested by Ingraham, Bailey and Nulsen, of pieces of fibrin foam soaked in thrombin may be necessary. Small cottonoid strips, cotton pledgets, special nerve root retractors, special rongeurs and biopsy punches are all of great assistance and represent part of the regular armamentarium of the neurologic surgeon.

The most debated question in the surgical management of these cases is that of whether *spinal fusion* should be combined with removal of the disk protrusion—the so-called “combined operation.” Opinions vary from the extreme that it should be done in every case of disk protrusion, to the other extreme, that it is seldom if ever necessary. Only time and further observation of the results in large numbers of cases can give the answer. For the present it is my opinion that the combined operation should be considered (1) in cases of multiple or recurrent disk protrusions, (2) where there is roentgenographic, clinical or surgical evidence of inherent instability of the lumbosacral spine, (3) where low back pain is severe and disabling for a long period before the onset of sciatic radiation, and (4) where the patient's occupation is one of heavy labor or demands a great deal of lifting.

Obviously the best interests of the patient are served by the full cooperation of neurologic and orthopedic surgeons, and it is no accident that the most advances and the best results in the management of these cases have come from those clinics and institutions where such cooperation is routine and where both the neurologic and orthopedic surgeons have contributed their share to the problem.

Postoperative Management—The length of time that a patient should spend in bed after the operation and the period of convalescence before returning to full activity are in my opinion very important points. Since any operative repair of the rupture of the posterior longitudinal spinal ligament or annulus fibrosus is not technically feasible, we are forced to depend on natural means—the proliferation of fibrous connective (scar) tissue—for the repair of these structures and the cavity in the disk left by the removal of fragmented nucleus pulposus and fibrocartilage. It is our practice to keep the patient in bed for two

weeks after the removal of a disk protrusion and then allow gradual resumption of activity. Light work may be resumed in six weeks, full physical activity especially heavy lifting or strenuous work, should be postponed for three months. Some will object to this claiming that such long periods of inactivity tend to destroy the patient's confidence in the result and to increase the number of patients with poor results. It is true, especially in compensation cases, that every effort should be made to discourage the development of an attitude of chronic invalidism. However if an adequate explanation is given the patient for the prolonged convalescence and if, after the prescribed period has passed firm insistence is made on resumption of activity, no serious difficulty should be encountered. Too often a surgeon fails to exercise adequate observation or control of the patient's activity during convalescence and is then disappointed at the patient's refusal to undertake immediate full activity.

MANAGEMENT OF MYASTHENIA GRAVIS

RICHARD RICHTER, M D *

PERHAPS the most gratifying advance in therapy in the field of medical neurology during the past decade has been in the treatment of myasthenia gravis. It is true that the underlying cause of the disease remains unknown and that no cure is in our hands, but the symptomatic relief which the new drugs afford in most cases is nevertheless remarkable. From an era in which all physicians stood virtually helpless before this truly grave and dread malady we have suddenly entered one in which we can not only prolong life and abolish severe distress for our patients but can even achieve a reasonably active life for many of them with considerable assurance. This progress has not been a matter of chance. While one of the important discoveries in the treatment of the disease, the use of ephedrine, was purely accidental, all the rest have resulted from well planned application of knowledge gained in the basic medical sciences, notably in physiology and pharmacology, to practical clinical problems. The whole story of the development of the modern treatment of myasthenia gravis stands as another shining and hopeful example of what may be expected of the intelligent union of theory and practice in the medicine of the future.

It is not intended to leave the impression that the newer methods insure the control of myasthenia gravis or have robbed the disease of all its terrors. For too many patients are refractory to treatment or become so, and either succumb sooner or later to failure of the respiratory muscles and its consequences or are so enfeebled that they are unable to earn a living or even take care of themselves in spite of all that can be done. But comparatively the progress made in treatment has been enormous.

DIAGNOSIS

A diagnosis of myasthenia gravis can be made in most cases easily and with a high degree of accuracy. In the average fairly well developed case this can usually be done from the signs and symptoms.

Signs and Symptoms—*Muscular weakness* is the presenting symptom of disease and, in its various manifestations, the only one. This in itself serves to differentiate myasthenia gravis from a number of neurological conditions in which motor weakness is accompanied by other

* Associate Professor of Medicine, University of Chicago, Attending Neurologist, Albert Merritt Billings Hospital

signs such as muscular atrophy, sensory disturbances or reflex changes. Characteristic of the weakness itself, and always suggestive of the diagnosis is the feature of *fatigability of the affected muscles* during sustained or repeated effort. A facial movement, such as baring the teeth may be done fairly well a few times in succession and then rapidly becomes more restricted until it is altogether impossible. If the weakness is in the upper extremity the hand-clasp at first may be rather strong only to vanish if it is sustained or repeated often. Asked to read or count aloud, a myasthenic patient may do so clearly at the start but soon the speech becomes slurred to the point that words become unintelligible and the voice loses volume until it is no longer audible. Recovery of the original strength usually occurs after a short rest, so that the patients often carry out their tasks by spurts of activity relieved by periods of rest. While the reflexes when first examined are almost always normal, they too, if the responding muscles are involved, may show this same exhaustion when stimulated repeatedly in rapid succession. Not infrequently it is impossible to demonstrate convincingly such sharp development of fatigue during the course of the examination but even in such cases the tendency is apparent in the history. The patient is stronger in the morning after a night's rest and becomes increasingly weak as the day passes, breakfast is eaten with relative ease but lunch and dinner become increasingly difficult to masticate and swallow, or increasing fatigue is noted during the individual meals. A housewife may be able to sweep one room but must stop to rest lest she drop the broom when halfway through the second.

The weakness not only possesses this characteristic quality but in the usual case betrays a characteristic localization as well which is diagnostic in itself. While the muscles of the extremities and trunk are often affected, it is those innervated by the *motor cranial nerves* which are most regularly involved. Among these in particular are the extrinsic muscles of the eyes, producing ptosis of the lids, strabismus and diplopia, the muscles of the face and the muscles of the pharynx and palate with the consequent slurred, nasal speech and choking and regurgitation on swallowing. In the case of all of these muscles the involvement is usually bilateral and more or less symmetrical, although isolated weakness of a single muscle, one external rectus, for example, is not uncommon. In more advanced cases it may also happen that one muscle or a group of muscles becomes totally and permanently paralyzed. This is especially apt to occur with the ocular muscles. The combination of ocular and facial involvement leads to the development of the "myasthenic facies" which is unmis-

takable a smooth, expressionless countenance, rendered drowsy from drooping of the eyelids and stupid from the fallen jaw and partly open mouth occasioned by weakness of the masseter and temporal groups. The lower facial muscles are often weakened in a peculiarly selective way so that in attempting to smile the upper lip is elevated, baring the teeth without retraction of the angles of the mouth. This results in a snarling expression instead of a natural smile, the so-called "*risus sardonicus*."

Special Diagnostic Tests—Even in typical cases it is desirable, and in some early or atypical examples of the disease it becomes necessary, to employ certain special confirmatory diagnostic tests. Of these by far the most useful and important is the prostigmine test.

Prostigmine Test—The basis of this procedure rests on the fact that most of the manifestations of myasthenia gravis are improved definitely and promptly by the action of prostigmine, an analogue of physostigmine. In a sense it is a therapeutic test that may be carried out in a few minutes. It is customary to give the patient 1 mg of prostigmine methyl sulfate subcutaneously. The drug is readily obtainable in ampules for parenteral administration. This dose is ordinarily adequate to produce satisfactory effects without leading to severe side actions. Within fifteen minutes the drug begins to take effect, it reaches its maximum activity in about half an hour and begins to wane after an hour. The patient first experiences a feeling of well-being and renewed strength and soon is able to carry out movements which a few minutes before were well-nigh impossible. The eyes can be opened and diplopia disappears, the patient is able to smile again, the speech loses its thickness and swallowing improves dramatically. The results are often spectacular and seldom fail to astonish the patient and even the physician. Any such clear-cut effect is pathognomonic of myasthenia gravis since it occurs in no other form of muscular weakness. Whether the failure of a decisive response excludes the diagnosis of myasthenia gravis is not so certain, but if such cases exist they are extremely rare. It occasionally happens, however, that some weakened muscle groups respond in this definite way while others, more completely paralyzed, such as the extrinsic ocular muscles, are little if at all influenced by the test. Since prostigmine, like other drugs of its group, is a powerful stimulator of the parasympathetic nervous system, distressing symptoms due to this side action are sometimes produced, especially bradycardia, abdominal cramps and nausea. These are readily controlled by atropine. Consequently it is well to give $\frac{1}{400}$ grain (0.006 gm) of atropine together with the prostigmine. It is of interest that while atropine abolishes the auto-

nonic action of prostigmine, it in no way interferes with its influence on the weakness of voluntary muscles

Curare Test—Curare when administered to normal subjects in proper dosage produces muscular weakness which closely simulates myasthenia gravis. Myasthenic patients are more susceptible to curare than non-myasthenic persons and experience an exacerbation of their symptoms when given doses of curare too small to be effective in individuals not suffering from the disease. Bennett has utilized this fact to devise a diagnostic test for myasthenia in which the patient is given intravenously one-tenth the dose of standardized curare principle which produces moderate generalized curare asthenia in normal individuals. A positive test consists in the appearance or aggravation of myasthenic signs. Since the drug is difficult to obtain and the procedure potentially hazardous without adding anything of importance to the diagnosis the test is not recommended.

Quinine Test—Quinine, like curare, tends to increase the weakness when given to patients with myasthenia gravis and may be utilized in this way to confirm the diagnosis. This, too, because of the unnecessary danger and discomfort to the patient, is not recommended.

Electrical Stimulation—The affected muscles of myasthenic patients become fatigued when subjected to prolonged stimulation with an electric current just as they do from sustained volitional or reflex contraction. Instead of the enduring tetanic contraction seen in normal muscles the tension in the muscles fades to nothing during faradic excitation and the muscle does not again respond until a period of rest has intervened. This is the "myasthenic reaction" of Jolly, quoted widely in the textbooks. It forms an interesting sign of myasthenia and is a useful but not a necessary aid in diagnosis. The physician in general practice without the necessary apparatus or experience in electrodiagnosis to carry out this test is at no real disadvantage in the diagnosis of myasthenia.

Biopsy of Muscles—In a considerable number of patients with myasthenia gravis examined postmortem the muscles exhibit rather characteristic infiltrations of round cells, resembling lymphocytes. It is sometimes possible to find these so-called "lymphorrhages" in muscle biopsies. But as a diagnostic measure the procedure is cumbersome and uncertain and is rarely if ever needed.

TREATMENT

General Measures—Long before the current drug treatment existed it was recognized that rest is an important consideration in the care of myasthenic patients. For those who exhibit extreme weakness or

show such threatening symptoms as dysnea, periods of complete bed rest may be necessary. Other patients may be well able to do their ordinary jobs, perhaps with the aid of several rest periods distributed through the day. Under no conditions should the patients undertake strenuous physical activity, and programs of exercise or massage are not only useless but may be harmful. It is impossible to outline a regime to fit all patients, since the management of each case must be adapted to the individual circumstances and symptoms. It is a good general rule that patients should pause to rest whenever they become uncomfortably tired and avoid the type or amount of activity which makes them so. Muscle groups which are especially prone to weakness should be spared action so far as possible.

Certain specific symptoms may require attention. Thus, *intractable ptosis* great enough to obscure the patient's vision may be corrected by a support for the upper lid attached to the patient's glasses, a so-called spectacle crutch. Troublesome *diplopia* is best obviated by covering one eye by an eye patch or by pasting Scotch tape over one lens of the patient's glasses. In the case of patients with any appreciable degree of *bulbar weakness*, special attention must be given to the mode of eating. All food must be soft, vegetables puréed, meat ground, and so on, and the patient instructed always to eat slowly and carefully in order to avoid aspiration. In extreme cases feeding by nasal gavage may become necessary. If so the nasal catheter must be introduced with great caution, since it easily passes into the trachea in these patients.

Acute infections of all kinds, including the common cold, have a notoriously unfavorable influence upon the course of myasthenia gravis. Every possible precaution should be taken against contracting any infection. When feasible it is advantageous for patients to winter in warm, mild climates.

Formerly it was thought that *pregnancy* exerted a uniformly disastrous effect upon the disease. It is true that many women with myasthenia suffer severe relapses when pregnant. For this reason and because many of them are ill-suited to withstand the physical demands of parenthood it is in general wise for them to avoid conception. However, a number of instances are on record in which the disease has undergone striking remissions during pregnancy. Furthermore, relapses, which according to Viets are most common and severe in the first trimester of pregnancy, can now usually be controlled satisfactorily by drug therapy and therapeutic abortion avoided. This is desirable since abortion itself often aggravates the symptoms and has been fatal.

Emergency Measures—Profound weakness or paralysis of the respiratory muscles and aspiration of solids and liquids as a result of weakness of the muscles of the pharynx, epiglottis and glottis are the complications of myasthenia gravis most to be feared. Often these effects are combined and not infrequently lead to sudden and unexpected death. One of the most useful measures for combating such crises is prostigmine administered subcutaneously in doses of 1.5 or 2 mg., repeated as necessary. Every patient should be provided with ampules of prostigmine and a hypodermic syringe and the members of his family instructed in its use in case of necessity. During severe exacerbations it may be necessary to increase the basic dose of prostigmine and to employ not one but several or all of the accessory drugs used in the treatment of the disease, namely ephedrine, guanidine and potassium.

In cases of respiratory paralysis, nasal oxygen may be helpful. At times a respirator is required to tide a patient over such a period. When marked bulbar palsy is a threatening symptom, continuous suction applied to the nasopharynx via a nasal catheter is efficacious in preventing serious aspiration. Prompt bronchoscopy and clearing of the airways can be a life-saving measure after massive aspiration.

Drug Therapy—Prostigmine—It can be said that more or less continuous oral medication with prostigmine is by all odds the most dependable and satisfactory means of controlling the symptoms of myasthenia gravis and that it forms the sheet-anchor of the management of most cases. In order to appreciate the rationale of the treatment it is necessary to understand something of the mechanism of the motor innervation of striated skeletal muscle. It is now thought that the transmission of a nerve impulse to the muscle fiber is accomplished by a chemical reaction set up at the motor end-plate of the nerve fiber. The ester *acetylcholine*, is known to be produced at the muscle by stimulation of its motor nerve and there is reason to believe that it is this substance that activates the muscle to contraction. Almost immediately after its formation, *acetylcholine* is again destroyed by hydrolysis into acetic acid and choline, through the action of a substance known as choline esterase. This insures that the effect of *acetylcholine* on the muscle is brief, precise and phasic. It has been demonstrated further that prostigmine affects this system by inactivating or inhibiting choline esterase, thus enhancing and prolonging the action of *acetylcholine* upon the muscle.

From these facts it may be inferred that myasthenia gravis is a metabolic disorder affecting the chemical transmission of nerve impulses to muscles in such a way that the activating effect of *acetylcholine* is in some way blocked or lessened, and that prostigmine tends

to correct the balance by inhibiting the physiological antagonist of acetylcholine, choline esterase (Fig 33) It is improbable that the fundamental defect of the disease is an excessive concentration of choline esterase at the myoneural junction, since serum esterase con-

Fig 33—Diagram to illustrate the mechanism of the clinical transmission of nerve impulses to muscle and the mode of action of prostigmine in myasthenia gravis

A represents the normal state where nerve impulses in the motor neuron (MN) impinge upon the motor end plate (ME) releasing acetylcholine (AC), which reaches the muscle (MU) in sufficient amount to produce contraction. The excess acetylcholine is held in check or inhibited by choline esterase (CE).

B represents the situation in myasthenia gravis where the reduced or blocked acetylcholine, indicated by the small arrows, is insufficient to produce muscular contraction.

In C the effect of prostigmine (PRO) is shown. By withdrawing the influence of choline esterase, prostigmine allows enough of the weakened acetylcholine to reach the muscle to give a fairly adequate contractile response.

centrations are no higher in myasthenic patients than in normal controls and show no significant fluctuations with spontaneous changes in the severity of the disease. Choline esterase concentrations in the serum of myasthenic patients do decrease, however, after the admin-

istration of prostigmine and rise again when its symptomatic effects wear off. Whether the primary disturbance of neuromuscular transmission lies in a defective synthesis of acetylcholine or whether the action of acetylcholine on the muscle is blocked by some toxic substance similar to curare is not known.

The effect of parenteral prostigmine on the symptoms of the disease has already been mentioned. *Oral medication*, using the standard tablets containing 15 mg of prostigmine hydrobromide, also alleviates the symptoms, though less promptly and decisively, and is a more satisfactory method of continuous treatment. The effect of an oral dose of the drug begins to be felt within half an hour, reaches its maximum in about an hour and wears off in two or three hours. No

EFFECTIVE DRUGS IN THE TREATMENT OF MYASTHENIA GRAVIS IN ORDER OF THEIR IMPORTANCE AND USEFULNESS

Drug	Dose	Use	Side Actions	Control of Side Action
Prostigmine hydrobromide (Tablets 15 mg.)	60 mg. to 200 mg. a day in 3 to 6 divided doses	Primary control of muscle weakness	Nausea, abdominal distress and cramps, diarrhea	Atropine (1/100 gr 0006 gm.) or 1r belladonna 10 to 15 drops t. i. d.
Ephedrine sulfate (Capsules 3/4 gr.)	3/4 gr. (0.022 gm.) b.i.d. to t.i.d.	Supplementary to prostigmine	Nervousness, tachycardia and insomnia	Reduce dose or change to another drug
Guanidine hydrochloride (Tablets 125 mg.)	10 mg. to 25 mg. per kilo body weight in 3 or 4 divided doses	Supplementary to prostigmine if not satisfactory	Gastro-intestinal symptoms Nervousness and muscle twitching	Atropine Calcium gluconate
Potassium chloride	10 gm. t.i.d. in capsules	Supplementary to prostigmine if not effective	Gastrointestinal symptoms Diuresis	Bismuth subnitrate

fixed rule of dosage can be given. This must be determined individually for each patient. An average dosage for twenty-four hours is 6 or 8 tablets (120 mg.) taken at three-hour intervals. Some patients require much larger doses, up to 20 or 25 tablets (350 mg.). Optimum spacing of dosage is as important as the amount and must also be worked out for each patient. It is usually desirable to give the drug an hour before meals for the advantage it gives in chewing and swallowing. Some patients require a dose on retiring to carry them comfortably through the night. Temporary increase of the basic dosage may be needed to tide the patient over an infection or unavoidable stress and exertion. It is wise to keep the dosage as low as is compatible with reasonably satisfactory results since there is some tendency for patients to experience an increase of symptoms and become re-

fractory to the drug after its effects subside, especially after large doses. Most myasthenics tolerate even large doses of oral prostigmine very well. Those who develop unpleasant symptoms from parasympathetic stimulation should be given tincture of belladonna, 10 to 15 drops with the prostigmine, or, if necessary, atropine, $\frac{1}{100}$ grain (0.0006 gm). This will control abdominal cramps and other toxic symptoms effectively and rarely needs to be continued more than two or three weeks after medication is begun.

Ephedrine—Ephedrine was used for its beneficial effect upon myasthenic symptoms after the accidental discovery of its usefulness by Edgeworth in her own case, several years before the introduction of prostigmine. Fairly satisfactory results were obtained in a number of patients from its use alone. At the present time it is employed chiefly as an adjunct to prostigmine. For most cases it is the most effective supplementary treatment available. It acts to fortify, prolong and smooth out the action of prostigmine. Capsules of ephedrine sulfate, $\frac{3}{8}$ grain (0.022 gm), given two or three times a day between the doses of prostigmine are usually an effective and satisfactory way to prescribe the drug. Some patients obtain better results by smaller doses given at more frequent intervals. In this case it is convenient to use the prescription recommended by Boothby

Ephedrine sulfate
Normal saline

gr viii (0.53 gm)
℥ viii (240 cc)

A teaspoonful of this mixture, which contains a dose of $\frac{1}{8}$ grain, is given four or five times a day. It is well not to prescribe ephedrine in the evening because of its tendency to produce insomnia, particularly since sedatives should be avoided, if possible, in all myasthenic patients. Amphetamine (Benzedrine), which has other actions similar to ephedrine, gives little or no relief from myasthenic symptoms.

Guanidine—Following the experimental demonstration that guanidine increases the sensitivity of muscle to acetylcholine, this drug was used for the treatment of myasthenia gravis. It has a beneficial effect in some, but not all, cases and, like ephedrine, is utilized principally to enhance the action of prostigmine. It is best administered by mouth in tablets containing 0.125 gm of guanidine hydrochloride. As an initial dose, 10 mg per kilo body weight per day divided into three or four doses is recommended. The amount and distribution of dosage must be determined for each patient. Doses of 25 mg per kilo per day can be given safely and doses as high as 45 mg per kilo per day have been employed in severe cases. Myasthenic patients are more tolerant to the drug and less apt to develop toxic symptoms than are

those not having the disease. When such symptoms occur, they either take the form of nausea, abdominal cramps and other gastrointestinal disturbances which are readily controlled by atropine, or appear as nervousness and muscular twitching, which can be counteracted by giving calcium. Guanidine is less reliable and effective, in general, than prostigmine or prostigmine with ephedrine, but may be useful in cases that do not respond well to the latter treatment.

Potassium—The use of potassium salts for the treatment of myasthenia gravis was suggested by the fact that potassium increases the effectiveness of acetylcholine on muscle by about 50 per cent and tends to counteract the paralytic action of curare. It is never as effective as prostigmine and cannot be used alone in the treatment of myasthenia with satisfactory results. It may be employed to enhance and prolong the effect of prostigmine and to reduce the prostigmine requirement when ephedrine or guanidine fail to do so. Even for this purpose good results are obtained only with very large doses, that is, 10 to 12 gm. of potassium chloride given three times a day. This is one of the principal disadvantages of the treatment since such amounts of potassium lead to very distressing gastrointestinal symptoms and urinary frequency in most patients. The nausea, abdominal distress and diarrhea are best controlled by administering the potassium chloride in some such mixture as the following, suggested by Talbott and Schwab.

1 qt. milk
1½ cup cream
1 egg
2 teaspoonfuls of sugar
8 teaspoonfuls (30 gm.) of potassium chloride

This eggnog is made up daily, kept in the refrigerator and taken in three divided portions. Two teaspoonfuls of bismuth subsalicylate may be added to it. If so, it should be well shaken before taking.

The precise mechanism of the effect of ephedrine, guanidine or potassium upon the weakness of affected muscles is not well understood. It evidently does not depend upon inhibition of choline esterase as is the case with prostigmine.

Glycine—Amino-acetic acid (glycine) has been reported to be beneficial and has been used extensively in the treatment of myasthenia gravis, especially before the advent of prostigmine. It is given customarily in doses of 20 to 30 gm. a day preferably in milk. In my experience it has never been effective except when ephedrine or prostigmine has been given at the same time and it is my opinion that it is of no benefit whatever.

Endocrine Therapy—Inasmuch as myasthenia gravis can now be classed as a metabolic disease, and as it often shows striking fluctuations in relation to menstruation and pregnancy and there are reasons to believe that it may be related to some hypothetical activity of the thymus gland, it is only natural that many attempts have been made to treat the disease with a wide variety of endocrine substances. These include thyroid extract, thymus extract, adrenal cortical substance, antophysin, estradiol dipropionate, testosterone propionate, progesterone and other sex hormones. There is almost general agreement that none of these substances is of value in myasthenia.

Surgical Treatment—During the past few years increasing interest has been attracted to the treatment of myasthenia gravis by the removal of a persistent or hyperplastic thymus gland or occasionally a thymic tumor. The lead to this approach in therapy has been taken from the pathological experience that about half the cases of myasthenia gravis that have come to autopsy have shown some abnormality of the thymus, either in the form of hyperplasia, benign thymoma or, rarely, malignant thymic tumor. Thus, of ninety-five instances of lesions of the thymus in myasthenia gravis found at operation or autopsy, forty-two were classified as simple hyperplasia, forty-seven as benign thymoma and six as malignant thymoma. It should be borne in mind, however, that from the pathological standpoint the distinction between hyperplasia and benign thymoma is not a sharp one and that there is no histological uniformity in the type of thymic hyperplasia encountered in myasthenia gravis. In some cases this appears as an increase of epithelial tissue, in others as proliferation of the lymphocytic elements of the thymus.

The early attempts at thymectomy, beginning with that of Sauerbruch in 1912, were disappointing from an operative standpoint. Modern technical developments in thoracic surgery and improved methods of postoperative care have made possible successful thymectomies in a small but notable series of myasthenic patients. In twenty-eight thymectomies reported in the recent American literature there were only five deaths. This is an excellent record if one considers the fact that patients with myasthenia are, in general, poor surgical risks.

Following the operation there appears to have been striking improvement in a number of the patients, amounting virtually to a cure of two to three years' duration in a few. When the case histories of the twenty-three patients who survived the operation are examined critically, and even when the cases recorded as only moderately improved are excluded, there remain seven who are obviously much better and do well on greatly reduced doses of prostigmine and five

who lead normally active lives with little or no medication. Such reports must be judged with great caution and even skepticism in view of the tendency which the disease sometimes shows for long spontaneous remissions. Moreover it would appear most unlikely that abnormality of the thymus is the primary or essential basis for the disease, when only half the cases show any thymic abnormality and some cases are in no way influenced by removal of the thymus. Nevertheless, the prompt and decisive improvement of symptoms almost immediately following operation in so many cases and the completeness and duration of the postoperative remissions in some cannot be disregarded. This form of treatment is still in the stage of trial and many more cases will have to be studied and longer postoperative periods elapse before its true worth can be estimated. It is a treatment, also, which can be undertaken satisfactorily only by experienced thoracic surgeons. It appears that patients with actual tumors of the thymus are more apt to receive marked benefit from the operation than those with simple hyperplasia. If one can speak of indications for the procedure at this stage of its development, it seems that one would choose patients in whom an anterior mediastinal tumor can be diagnosed by x-ray or patients who remain seriously incapacitated by the disease in spite of adequate medical management. Ordinary thymic hyperplasia can rarely, if ever, be diagnosed by x-ray and even thymic tumors may be extremely difficult to demonstrate and require careful fluoroscopic study and lateral chest films in addition to the usual ones.

Roentgen therapy of the thymic region has been carried out in many cases of myasthenia gravis with most conflicting and inconclusive results. There would seem to be no contraindication to trying it.

SUMMARY

Myasthenia gravis is to be regarded as a metabolic disease in which the transmission of the motor nerve impulse at the myoneural junction is blocked by interference with the action of the transmitter acetylcholine, upon the muscle fiber. The disease is characterized by rapid, more or less reversible muscular exhaustion and weakness or even by paralysis which selects by preference the bulbar and ocular muscles. Consequently the cardinal signs are those of ptosis, strabismus, diplopia, dysarthria, dysphagia and difficulty in chewing. The diagnosis can be established with a high degree of certainty by the prompt and decisive improvement of symptoms induced by prostigmine. One milligram of prostigmine methyl sulfate is used subcutaneously for this purpose.

The most satisfactory medical management for the average case consists in the oral administration of prostigmine hydrobromide in doses of from 60 to 200 mg a day in divided doses. The optimum dose and its spacing must be determined for each patient. Often the prostigmine can be supplemented to advantage by ephedrine, guanidine or potassium.

General hygienic measures, in particular the avoidance of undue physical exertion and strain, form an important part of the therapeutic regime of every patient.

Roentgen irradiation of the thymus gland is of questionable value but it probably is worth a trial, at least in cases refractory to medical measures. In selected cases surgical removal of the thymus gland may be considered.

PERIARTERITIS NODOSA

GEORGE W SCUPHAN, M.D.* AND JANET R KINNEY, M.D.†

PRESENTATION OF A CASE

This patient was admitted to the hospital complaining of a sprained ankle of three weeks' duration. Additional complaints were fever, weakness and increasing difficulty in breathing for two months. She had had numbness and burning pains in both the right foot and hand. Her family was concerned about the swelling of her face and eyelids which had become quite marked.

The patient had been under observation as an ambulatory patient for a year and a half prior to this admission. When she first consulted us, she said that she had had hypertension for eleven years and the symptoms suggestive of angina of effort for a year. Her main complaint was difficulty in breathing. On frequent observations her blood pressure was slightly elevated and varied from 140 to 164 systolic and 100 to 110 diastolic. There was moderate enlargement of her heart but no other significant findings. Her chest was emphysematous, and the breath sounds were characteristic of a mild asthmatic bronchitis. This became really troublesome only when complicated by acute respiratory infections. The allergic factor was corroborated by an eosinophilia of 8 per cent and the finding of nasal polyposis. Following removal of the polyps, and on other treatment directed at her pulmonary pathologic condition, she improved and was able to carry on normal activity. In February of 1944 she went to the southwest. Her white blood count at this time was 9600 with 8 per cent eosinophils. Six weeks later in New Mexico, because of the appearance of low fever and increasing asthma, her count was rechecked and found to be 19 000 leukocytes with 65 per cent eosinophils. No other abnormal cells were noted. Shortly after this she developed the weakness, numbness and pain in the foot which brought her to the hospital.

On admission to the hospital *physical examination* revealed a moderately ill 55 year old white female. There was periorbital edema of the lids. The eye reflexes and extraocular movements were normal. The eye grounds showed mild hypertensive retinopathy with only minimal nicking of the veins. The nasal mucous membranes were pale and boggy. The throat and pharynx were normal. The thyroid was not enlarged. The chest was emphysematous in contour and expiratory wheezes and loud coarse rales were heard throughout the

† Clinical Assistant in Medicine, Northwestern University Medical School.

lung fields The heart was slightly enlarged to the left, the rhythm was regular, the rate 90, tones good, and no murmurs were heard The blood pressure was 130/90 The abdominal findings were essentially negative There was a right footdrop, the right ankle jerk could not be elicited and the right knee jerk was diminished There was no sensory impairment, and no muscular tenderness The bones and joints showed no abnormality

The most significant *laboratory finding* was a white count of 38,600 with 61 per cent of eosinophil leukocytes On repeated counts eosinophilia was always over 45 per cent There were no immature or abnormal forms The red count was 4,860,000 and the hemoglobin 14.6 gm, anemia has never been a factor Urinalyses were repeatedly normal There was no nitrogen retention The spinal fluid findings were normal

X-ray examination of the chest revealed a heart of approximately normal size The appearance of the lung fields suggested emphysema, with an increase in peribronchial markings with linear striations all the way to the chest wall The diaphragm was low and nodular Gastro-intestinal x-ray examinations were without significance

An *electrocardiogram* revealed no significant deviation from the normal other than left axis deviation with depression of the T waves in the precordial leads only This pattern has been unchanged during the period of observation

Examinations of the stools at numerous intervals because of episodes of diarrhea were unrevealing except that on several occasions enteromonas hominis were reported At no time was blood encountered, nor was there other evidence of bleeding *Sputum examinations* showed eosinophil cells, but no constant characteristic organism Clotting activity, bleeding and coagulation times were normal

The *sedimentation rate* of the erythrocytes was 32 mm per hour

Because of the marked eosinophilia, periorbital edema which was striking, and some diarrhea, trichinosis was considered the probable cause of her symptoms An intradermal test with trichinella extract produced an immediate well marked wheal reaction Even though there was no definite muscle tenderness, and in spite of the mild localized peripheral neuritis, the diagnosis of trichinosis seemed to be justified The patient was discharged after a stay of fifteen days in the hospital During this period, her temperature showed a daily average rise to 100° F Her asthma improved under the therapy employed and the patient was told that she would improve spontaneously as patients with trichinosis usually did

However, instead of the improvement expected, the patient became more and more uncomfortable The peripheral neuritis became more annoying Footdrop developed in the other foot, and became complete in the left so that the patient could not walk Numbness and burning pain in the left hand became almost unbearable She became emotion-

ally unstable, and wept because of the progressive increase in her symptoms. The asthma became worse, and after a few days almost intractable. Diarrhea of mild severity again made its appearance.

The patient was readmitted to the hospital after about one month at home during which time she had failed considerably. There was a daily rise in fever to a maximum of 102° F which showed a gradual decline with improvement in the asthmatic state. This was best controlled by the intramuscular injection of aminophylline in doses of $3\frac{3}{4}$ grains (0.23 gm) at four-hour intervals. The amount of sputum was large, and with the increased bronchial drainage, the temperature declined to a level below 100° F. One subsequent rise to 103° F for a few days seemed to be associated with an episode of respiratory infection and exacerbation of asthma. Other than this, the only symptoms were intermittent diarrhea and those associated with the increasing severity of the peripheral neuritis.

In view of the protracted course, the eosinophilia, the increasing prominence of the neurologic findings in the absence of any marked muscle tenderness, and the evidence of involvement of cardiac, pulmonary and gastro-intestinal symptoms the diagnosis of periarteritis nodosa was considered. The patient submitted to muscle biopsy. At operation there was no evidence of inflammation. The gastrocnemius muscle was purple in color rather than red, and appeared flaccid. A portion of this muscle was removed and an additional portion from the soleus.

The *histology* of these tissues was reported by Dr. Edwin F. Hursh as follows: "The tissues from the left soleus muscle have the usual skeletal muscle fibers and supporting fibrous stroma with a little fat. There is no acute exudative inflammation of the muscle tissues proper nor are trichina larvae present. The walls of the medium sized arteries have an acute or subacute exudative inflammation, distributed in varying degrees mainly in the outer portions of the wall. This exudative inflammation consists of infiltrations of polymorphonuclear leukocytes, most of them with eosinophil granules, a few lymphocytes and small numbers of fibroplastic cells. These reaction changes are not distributed uniformly. At levels of rather marked changes, the inflammation involves considerable of the perivascular stroma and other adjacent structures. The tissues from the gastrocnemius also have skeletal muscle fibers without trichina larvae. There is an acute or subacute exudative inflammation of varying intensity of the outer portions of the walls of the medium sized arteries."

Neurologic examination by Dr. R. P. Mackay was recorded on May 27, 1944. There were no cranial nerve palsies, but poorly sustained nystagmus on lateral gaze right and left. Left wrist drop was present, with good grip. Flexion and extension of the elbows and pronation and supination were normal on both sides except supination on the right. There was right footdrop with marked weakness of ankle ex-

tension on the left All proximal movements in the lower extremities were powerful Reflexes were good in the upper extremities Knee jerks were barely elicitable, and the left ankle jerk was similarly reduced, the right was absent All hamstring reflexes were good No pathologic reflexes were noted, nor was there any sensory impairment There was remarkably little tenderness of the extremities

Dr Mackay's comments were "The significant neurological feature is the discreteness of the peripheral neuritis, that is, the disseminated severe peripheral nerve lesions with other well preserved peripheral nerves"

Treatment of this case has been largely symptomatic Asthma was controlled by use of aminophylline parenterally For the diarrhea kaolin, belladonna, paregoric and vioform were used from time to time all with some success Thiamine hydrochloride was given in large amounts

Because of the exudative character of the disease it was decided to use large amounts of sodium salicylate These the patient tolerated well even in amounts up to 10 gm daily

Orthopedic measures for the control of footdrop have been helpful in preventing contractures and in the comfort of the patient Light removable plaster splints, comfortably padded, support both feet

The *subsequent course* has been that of slight improvement The neurologic findings have remained essentially the same, there has been no further loss of function, in fact, some movement of the toes of the right foot, the one first involved, has been noted The subjective symptoms of numbness and paresthesias have not been so conspicuous a part of the daily complaints, and in the hand have largely subsided The asthma is still an occasional problem but is fairly well controlled at present Although we have controlled the infestation with *enteromonas hominis*, there are still occasional episodes of frequent loose stools

In general the patient's condition has improved, at least the disease seems to be no longer progressive although the feature of leukocytosis with marked eosinophilia persists She is at home, able to be up in a wheel chair

COMMENT

There are several features of this case which are of particular interest The first is that of marked eosinophilia, which with the periorbital edema originally led to the erroneous diagnosis of trichinosis The positive and quite characteristic skin test with the trichinella antigen was confusing It cannot be readily explained unless the view can be accepted that periarteritis nodosa is a disorder manifested by

extreme sensitization which becomes general because of its intensity.¹ The extreme eosinophilia is evidence of this. Such an experience as this would suggest that muscle biopsy be done in each case in which trichinosis is suspected. It is easily done, and it requires no special technic to demonstrate the organisms. They are to be seen in fresh tissue without staining when the muscle fibers are compressed between two fairly heavy pieces of glass. These are examined under the low power of the microscope.

Incidence—Periarteritis nodosa has been considered a rare disease. Until 1935 about 150 cases had been reported, twenty in the American literature.² Since then numerous cases have been reported each year so that the total number is many more than twice the figure given. That the disease is much more common than the case reports indicate must be true. Many cases are no doubt unrecognized since the clinical pattern so often is characterized by visceral manifestations of wide variety. Most often when the diagnosis has been made, it has been at autopsy, and in the total deaths in the United States postmortem examination is exceptional. No doubt, since recovery has been reported, many more cases escape recognition.³

Etiology—The etiology of the disease is obscure, and a wide variety of theories as to its cause have been advanced. Many cases have been associated with infection^{4, 5, 6} as well as with rheumatic fever.⁷ The clinical association of the disease with bronchial asthma has been most frequently commented on^{7, 8} and the frequency with which high eosinophil counts occur also lends support to this view. The work of Rich¹ on hypersensitization adds weight to this theory. Krupp⁹ has noted the similarity between this disease and lupus erythematosus, Libman-Sachs disease and rheumatic fever. All seem to present some manifestations of tissue sensitivity, each in a different way. In the present case, allergy has been a constant manifestation, whether a causal or coincidental factor, it is not possible to say. The frequency with which asthma has been reported suggests that it is more than coincidental. It is possible that it may be a visceral manifestation that is, merely a manifestation of a vascular disease affecting the pulmonary structures.

Pathology—The pathology is well established. Arkin has described four stages: (1) the alterative degenerative or beginning stage, (2) acute exudative inflammatory stage, (3) the stage of granulation or healing, (4) the stage of fibrotic scar tissue or end stage. Our case would fall into the second stage of Arkin. Karsner¹⁰ found that necrosis and exudation are the most frequent types of pathologic change seen in the vessels. In typical cases the cells of the exudate include

both polymorphonuclear and mononuclear eosinophils. As a result of necrosis in the vessel walls, hemorrhage may occur, and small aneurysms frequently are a characteristic feature. The disease is one of the vascular system, specifically of the arteries. Hence, the same lesions have been noted in every structure of the body, sometimes predominating in one location or organ, sometimes, as in this case, in the peripheral vessels.

This wide dissemination would account for the great variety of clinical manifestations. Most accounts have emphasized involvement of the heart, kidneys, lungs, abdominal viscera, particularly frequent have been the manifestations of renal disease which are absent here. Carr¹¹ reported a case which was essentially limited to the lower extremities and in which gangrene developed early. This is most unusual. The symptoms in each case are those which occur as a result of disturbance in function of the viscera or structures involved by the pathological process.

That this case presented cardiac involvement is evident. One of the initial complaints was that of mild angina of effort and it was this which led the patient to seek medical aid. Pulmonary disease in the form of asthma has been a prominent symptom. The patient has had diarrhea of undetermined origin. True, there was another explanation for it, but the diarrhea has persisted in spite of the control of this factor. There were no abnormal findings in the colon x-ray, and sigmoidoscopy was not done. Felsen¹² made the diagnosis by sigmoidoscopic examination in one case prior to death. He noted peculiar horizontal linear dark red streaks running in parallel lines in the rectosigmoid area. Careful study with a telescopic device revealed that these lesions were within the vessels. Examination at autopsy confirmed those findings.

Attention has been called to the frequency of pains in the arms and legs, particularly tenderness as an outstanding group of symptoms. These were absent here, but certainly there were equivalent symptoms of nerve involvement in the numbness, tingling and burning sensations of which the patient complained so bitterly. Peripheral neuritis has been described, but not as a frequent feature of the disease.⁷ Kernohan and Waltman¹³ reported five cases in which the neurologic features of the disease were emphasized. Involvement of the peripheral nerves was quite common in this group. Cranial nerves may also be involved, and therefore, blindness, diplopia, deafness, facial paralysis and dysphagia may be part of the pattern. The central nervous system may also be involved, and this has frequently been re-

ported (cerebral hemorrhage and thrombosis have been particularly common

The anatomical association of the peripheral nerves with the arteries and veins in the same sheath in the extremities explains the occurrence of peripheral neuritis in this case. Obviously, the inflammatory reaction in the walls of the arteries extended to involve the adjacent peripheral nerves wherever the inflammatory reaction was extensive. Dr. Hirsh noted the tendency of the exudate to occur in localized regions along the course of the vessels. This would then also account for the isolated nerves involved, quite in contrast to the general peripheral neuritis of deficiency or toxic disease.

Diagnosis—The diagnosis in this case should, and could, have been made much sooner had we not been led astray by the idea that trichinosis offered the best explanation. It was proper to consider it in the diagnosis but this patient presented at the time of her first admission to the hospital all the features characteristic of periarteritis nodosa in that she had the involvement of multiple structures throughout the body so characteristic of disseminated vascular disease. She did not have all of them, but in connection with fever, leukocytosis, eosinophilia and allergy, the clinical pattern was fairly complete.

If we bear this pattern in mind, the clinical diagnosis of this disease can be made more frequently. When skeletal muscle involvement can be demonstrated, the diagnosis can be confirmed by biopsy with relative ease.

Treatment—Treatment of this disease must of necessity be symptomatic, first, because its etiology is not known and, second, because of the wide variety of symptoms requiring control for the comfort of the patient. This is well illustrated in the present case by the anginal syndrome, asthma, enteritis and peripheral neuritis. The only therapy which could be considered to have any bearing on the characteristic pathologic findings was the use of sodium salicylate. This drug was given because of the exudative character of the disease, and its similarity in this respect to rheumatic fever.

The results of therapy are difficult to evaluate because of the uncertainty of the clinical course, which often consists of natural remissions and exacerbations, the remissions in particular may continue for months or even years.⁴ It is therefore, not reasonable to conclude that the improvement noted thus far in this case is the result of salicylate therapy, but it appears to be rational, and seems to have contributed to the comfort of the patient, at least.

The ultimate outcome of any case of periarteritis nodosa is uncer-

tain, apparently some patients recover, but the vast majority of reported cases have terminated fatally

CONCLUSION

In conclusion, it can be said that periarteritis nodosa is a disease of the vascular system, particularly the medium sized arteries. The symptomatology is dependent upon the viscera, or structures involved, and these are usually multiple. Asthma is often associated. Eosinophilias of varying degrees are common. Its course is extremely variable, and its prognosis uncertain, most reported cases have terminated fatally. The diagnosis may be made clinically if the essential character of the disease is borne in mind.

THE MODERN CONCEPT OF SCHIZOPHRENIA

L. J. MEDUNA, M.D.,* AND W. S. McCULLOCH, M.D.†

IN contemporary psychiatry, schizophrenia is the misleading and misused name of most perplexing mental diseases. The difficulty in distinguishing the diseases has led to an ever widening application of the term until it now embraces all but a few mental disorders. Today such symptoms as catatonia or delusions or ideas of reference have become synonymous with schizophrenia. All this has happened since 1910, but to understand the difficulty we must go back into the history of psychiatric ideas.

VESANIA

Prior to the beginning of our psychiatry, physicians had distinguished four kinds of mental derangements: (1) mental enfeeblement, due to organic diseases, (2) partial madness, including *paranoia vera*, *neuroses* and *hysteria*, (3) *delirium*, or total madness associated with fevers, and finally, (4) the *vesania*, or total madness without *delirium* or fever. Modern psychiatry began with the conception of a psychosis as a disease consisting of a threefold unity—one etiology, one symptomatology, one course. In 1851, Falret¹ described (1) *folie circulaire*, now called the manic-depressive psychosis. In 1868, Sander described (2) *paranoia*. In 1874, Kahlbaum² published a description of (3) *catatonia*, and Hecker, who had collaborated with him for eleven years, that of (4) *hebephrenia*. There remained (5) *vesania typica*, characterized by fragmentary and fading delusions and a lack of appropriate feeling or emotion, and (6) *dysthymia*, consisting of *melancholias* and profound psychoneuroses.

To any one familiar with these descriptions of *hebephrenia* and *catatonia*, it is scarcely necessary to say that those diseases bore little resemblance to the cases now diagnosed *catatonic* or *hebephrenic schizophrenia*. *Catatonia* and *hebephrenia* began with a period of depression passing into excitement. Then came the symptoms that gave them their names. *Thereafter, the catatonics frequently died. If not, they either remained demented or remitted, whereas the hebephrenics*

regularly went into a silly dementia which was usually complete within eighteen months. Both diseases were characterized from the outset by a loss of affectibility—i.e., the patient's feelings and emotions were not determined by what happened to him or to those for whom he had cared.

Kahlbaum's greatest contribution was that he separated, out of the *vesania*, the *dementia paralytica*. This makes it permissible to refer to all the derivatives of the *vesania* as functional diseases. Such was the psychiatry which both *Kraepelin*³ and *Adolph Meyer*⁴ inherited. Their reactions to it were opposite. Disgusted by the perplexing mixture of symptoms and their fluctuations, which made diagnosis of psychoses the most difficult and fallible of the arts of medicine, *Adolph Meyer* produced a perfectly consistent and universally applicable system of nomenclature based on the most prominent psychobiological features of his patients' disorders. The holistic implications of this Linnaean classification have bridged the dualistic chasm in psychiatry for many an unsuspecting Cartesian and prepared physicians for psychoanalytic emphasis on interpersonal relations. Unfortunately, the biology was not pushed analytically into pathophysiology to determine the significant physical or chemical changes in any form of *vesania*. Being purely descriptive, it presented no obstacle to the spread in the use of the supposedly interpretive term *schizophrenia* to any and all types of *pathergasias*.

Adolph Meyer's antipathy to the *Kraepelinian* approach is probably best put in his own words: "The man who did not know or mind the fact that he diagnosed wrongly two out of every three cases stamped by him as *paresis* undertook to tempt the world into thinking in terms of a diagnostic wish-fulfillment, so as to jump from one type of confusion and complacency into another type of confusion and challenge. Instead of letting medical progress and mastery of facts and destiny lead, *Kraepelin* satisfied himself and large numbers of physicians with the interest in end-results and flattery of the power of fortune-telling, and the challenge of a unitary conception for the problem of deficiency formation, in other words, the problem of bankruptcy of both patient and physician."

DEMENTIA PRAECOX

Yet it is to *Kraepelin's* insistence on the "unitary conception of deficiency formation" that we must now look for the description of the fundamental traits from which the conception of *schizophrenia* evolved. It is not to be found in *Kraepelin's* first book, published in 1883, in which the classification lacks unity—etiologic, prognostic or

pathologic Although it calls attention to heretofore neglected aspects of psychoses, it adds little to the nosology inherited from Kahlbaum But in the fourth edition, 1893 the triadic unity of a psychosis appears. His description of dementia praecox, a term previously used by Morel for another condition, remains one of the few unmoved foundation stones of psychiatry Here for the first time are made those distinctions which Bleuler used later in defining schizophrenia Dementia praecox, in the fourth edition, appeared in place of hebephrenia in the same rank as catatonia Only later did it include the catatonic, paranoid and simple types with the hebephrenic under a single caption, and then only because Kraepelin was convinced that they had the same etiology, course and defining symptomatology He originally thought that there must be a degenerative pathology but in 1896, he termed it a metabolic disturbance of as yet unknown nature Because of the invariable outcome "permanent peculiar enfeeblement," he gave it the name dementia praecox He says, "We are able now, at the beginning of an illness, to predict its resulting in a characteristic state of feebleness"

To do this required, first, that one distinguish between transitory and fundamental symptoms, for the diagnosis rested on two and only two, fundamental symptoms In 1893, Kraepelin said "Compared with these, all other disturbances, however prominent they may be in individual cases must be regarded as merely transitory and therefore not absolutely diagnostic features This holds good, for instance, of delusions and hallucinations, which are frequently present, but may be developed in very different degrees or altogether absent or disappear, without the fundamental features being in any way affected"

The core of the disease is a specific deterioration characterized by these two fundamental symptoms, "the peculiar and fundamental want of any strong feeling of the impressions of life" and "impaired ability to understand and to remember," which amounts to "a weakness of judgment and flightiness although pure memory has suffered little if at all", and again "We have a mental and emotional infirmity to deal with—the infirmity is the incurable outcome of the disease" By "mental infirmity" or "feebleness of judgment," it is clear that he did not imply any deficit of information or comprehension, but rather a disorder of evaluation, and similarly, by "emotional infirmity" that he did not imply a want of feeling and emotion, but rather a lack of interest and affection, for he says, "the faculty of comprehension and the recollection of knowledge previously acquired are much less affected than the judgment and especially than the emotional impulses and the acts of volition which stand in closest relation to those im

pulses The complete loss of mental activity, and of interest in particular, and the failure of every impulse to energy, are such characteristic and fundamental indications that they give a very definite stamp to the condition Together with the weakness of judgment, they are invariable and permanent fundamental features of dementia praecox, accompanying the whole evolution of the disease "

SCHIZOPHRENIA

From external and internal evidence, it is clear that this description of dementia praecox by Kraepelin was the foundation stone of *Bleuler's* definition of schizophrenia on the tenth page of his first book published in 1911 ⁵ He says nothing of the etiology in that definition, but specifies the malignant course which never permits "*restitutio ad integrum*" Regarding all other symptoms as accidental, he rests his diagnosis of schizophrenia on what he calls three basic criteria (1) a characteristic disturbance of associations, which is equivalent to the aforementioned weakness of judgment, (2) a disturbance of "*Affektivitat*," comparable to the loss of interest and affection So far the term is almost synonymous with dementia praecox, but to this there is added a third criterion, (3) the lack of primary disturbance of perception, orientation, memory, or, broadly, the lack of any disturbance of the sensorium This third diagnostic criterion, had it been rigorously applied, would have divided the pictures called dementia praecox into two groups, which would, we believe, have been very helpful, but it happened otherwise

The characteristic defect in the association of ideas, according to Bleuler, is their looseness which makes thinking incoherent, incorrect and bizarre or obstructs it altogether If the sensorium be clear, it is difficult to attribute this so-called looseness of associations to anything except disordered valuation, which may ultimately depend upon defective interest and affection This would seem to be indicated by the most careful work done by psychologists and psychiatrists, for it has failed to indicate any formal defect not so explainable

The disturbance of "*Affektivitat*" has been translated by many as disturbance of "affectivity," although no such word is to be found in the Century or the Oxford English Dictionary It is certainly more inclusive than "affectibility," which implies that something matters to the patient From Bleuler's use of the word, it appears to be synonymous at times with emotion, at times with feeling as opposed to reason, and at times with mood, humor or disposition The pathological changes include at least (1) a raised threshold (decreased affectibility or indifference to externals), (2) prolonged latency, (3) abnormal

persistence, (4) lability, (5) incompatibility with concurrent events, (6) incongruities among themselves. Thus, Bleuler's second criterion is less specific than Kraepelin's, which can be translated as loss of "affect," an English word that has been defined as that feeling, emotion or passion which is brought about in us by an (external) influence. From the lack of specificity of Bleuler's second basic criterion springs a part of the difficulty in keeping the term schizophrenia within bounds, for it is difficult to imagine any form of behavior under any circumstances which could not be considered to exhibit a disorder of "Affektivität" to a sufficiently unsympathetic observer. The third criterion, which in itself is excellent, contradicts the assumption that any and all accidental symptoms are irrelevant, for among them Bleuler numbers "hallucinations," "illusions," and "disturbances of perception," each of which, if it be real, implies some disorder of the sensorium. It is therefore not surprising that in the very book which begins with the diagnostic principles, Bleuler, a few pages thereafter, mentions twilight states and dazed conditions and the lack of "Besonnenheit," although "Besonnenheit" in German medicine means exactly the absence of clouding of the sensorium (cf. Lang's German-English Medical Dictionary). Its lack implies a clouded sensorium. Thence the confusion grew so rapidly that the original conception of schizophrenia of 1911 was lost by 1916 when Bleuler's second book appeared. We quote Brill's translation of the fourth edition: "Under schizophrenia are included many atypical melancholias and manias of other schools (especially nearly all 'hysterical' melancholias and manias), most hallucinatory confusions, much that is elsewhere called amentia, a part of the forms consigned to delirium acutum, motility psychoses of Wernicke, primary and secondary dementias without special names, most of the paranoid of other schools, especially all hysterically crazy, nearly all incurable 'hypochondriacs,' some 'nervous people and compulsive and impulsive patients.' The diseases especially distinguished as juvenile and masturbatory all belong here, also a large part of the puberty psychoses and the degeneration psychoses of Magnan. Many prison psychoses and the Ganser twilight states are acute syndromes based on chronic schizophrenia." As if that were not enough, Bleuler specifically includes the paraphrenias of Kraepelin and develops a concept of "latent schizophrenia" which can be brought to light by almost any deleterious external or internal condition. In his own words, "one may never directly exclude schizophrenia." So the term schizophrenia, originally less inclusive than dementia praecox which was but a part of vesania, came to be more inclusive than vesania, perhaps a synonym for crazy.

The confusion is not purely linguistic. Kraepelin and Bleuler and their successors saw cases, now catatonic, now paranoid or hebephrenic. They saw patients who clearly had the defect of judgment and loss of affect become delirious, and delirious patients lose judgment and affect as the sensorium cleared, and others who recovered or even improved upon their premorbid personalities. Any diagnosis implying prognosis was difficult and hazardous. On the other hand, the adjectives catatonic, paranoid or hebephrenic were easy to substantiate and these could all be applied to schizophrenia. So these accidental symptoms usurped the function of the criteria until, today, they are supposed to imply them, and the adjectives imply the noun, schizophrenia. The confusion is now so general that one student of psychiatrists noted "every patient should receive two diagnoses—first schizophrenia, and second, what is wrong with him." One need scarcely add that by the second he did not mean the psychobiological descriptive epithet, but the disease.

It would be difficult, therefore, for this institute to avoid the problem of schizophrenia. It has, in fact, been engaged for nearly a year in the attempt to evaluate Bleuler's original conception of schizophrenia, to sharpen its definition and to distinguish between cases fulfilling that definition and all other so-called schizophrenics, not by artificial classifications, but by conjoined clinical and laboratory observation of recognizable differences.

MODERN DISTINCTIONS

The suspicion that these patients suffer from distinguishable diseases began with Kraepelin. In the early twenties, Klesi⁶ had segregated a group suffering from what he called acute paranoid hallucinosis. They frequently recovered or totally remitted and had an acute onset and a true hallucinosis. These were the cases most frequently cured by "Dauerschlaf." In 1937, Meduna⁷ concluded that the cases which benefited from metrazol convulsions had "pseudo" schizophrenia, and suggested that the procedure might separate the "symptomatic" from the "true" or "endogenous" schizophrenias. He had then had three years experience with convulsive therapy and had begun to note clinical differences between the groups, most characteristic whereof was that "symptomatic" cases frequently experienced the disease as a dreadful change which filled them with a fear-like apprehension. This is the "process symptom" of Mauz. They tended to have spontaneous remissions and their good reactions to convulsions were accompanied by an exaggerated shift to the left in the white cell count—i.e., increase of neutrophils and basophils with decrease of eosinophils and

lymphocytes. The "transitory or secondary" symptoms were of no diagnostic value. Meduna, in Amsterdam, christened the recoverable group 'schizophreniform' and Langfeld⁸ used this name for them in his monograph where he refers to them as reactive as opposed to genuine, true or endogenous schizophrenia. His diagnostic symptoms are acute onset, a period of cloudiness and evidence of exogenous factors. In 1939, Meduna and Friedman⁹ noted that remitting patients frequently described their psychoses as 'like a dream'. The lack of reality of their experiences they compared with that of the theater and spoke of 'feeling as though everyone were playing a part—just acting'. The acute paranoid hallucinosis of Klaesi, the dreadful feeling or process symptom of Mauz, the 'period of cloudiness' of Langfeld and the 'dreamlike' quality of the pathologic experiences of Meduna and Friedman can all be understood if, and only if, there is a disorder of the sensorium. This is exactly what is excluded by Bleuler's third criterion. It separates schizophrenics from these, the remitting, the curable, cases. They are, by Bleuler's definition, not schizophrenics no matter how much they may in other ways resemble them.

To keep the distinction clear in the following instances, we state briefly three postulates:

- 1 Distinguishable diseases may produce indistinguishable pathologies. For diagnosis, one must look to the basic symptoms, not of the ultimate deterioration but of the onset of the psychoses.

- 2 Almost all specific nervous and mental symptoms indicate the location, not the pathological process. Thus, pupillary irregularities, reflex changes, furors, immobility, flexor spasms, echolalia, echopraxia, waxy flexibility and akinetic mutism may appear as a consequence of functional or structural failure of given parts of the brain in any injury or disease of those parts. Any diagnosis based on such symptoms only, is merely anatomic.

- 3 Projection—the attribution of the unwanted to parts of the world other than ourselves—is an essentially healthy reaction. We are all at times guilty of ideas of reference or persecution. The hammer gets blamed for hitting the thumb. The world is suspect to the insecure and the wound that will not heal is damned by the physician. Only depressions show the converse, and the failure to project frequently portends suicide. Regardless of its cause, a projected mental or emotional ineptitude becomes a paranoid trend. This substantiates the defect but does not give any clue to the diagnosis.

Thus, ultimate deterioration, localizing symptoms and paranoid reactions are useless when we wish to know the nature of a disease.

Case I "Schizophrenia" by Bleuler's Three Criteria

The "true" or "endogenous" schizophrenia as defined by Bleuler is exemplified in the history of Walter, who walked at eleven months, cut his first tooth at one year, was breast fed a little longer and talked at eighteen months. His family attributed his troubles to an automobile accident at three years of age in which he was frightened but not injured. His "nonsense talk" began some months later. It made conversation impossible and he was withdrawn from school. He interrupted anyone, screamed, attacked his parents and danced in excitement, but his memory was accurate and extensive. This picture had lasted three years before it brought him, in 1936, to Dr. Hamill, to whom we are indebted for permission to publish this abstract from his exhaustive study covering four years.

When first seen, Walter was six years old. His mental age (Binet-Simon) was at least six years, four months and his electroencephalogram was practically normal. His mental content was limited, speech fragmentary, response sometimes incoherent, more often irrelevant, and he repeated instructions before acting on them. Late in November, 1936, presumably because he had heard a rumor about a child killed in an accident in an elevator there, he became terrified when taken to a department store. He trembled, cried, vomited and remained "hysterical" for two days during which time he made little jerking movements of his body and shoulders and said scarcely a word. The following day, Dr. Hamill was for the first time able to make out that he failed to distinguish between himself (Walter) and water. Walter shifted to water, thence to Deanna Durbin who played in "Rainbow on the River" and so to water again. Being water, he felt he could not be drowned, but might be imprisoned in the radiator. On hearing the knocking of water in the radiator, he said, "elevator just came up and gave the kid a knock" and again, "they are killing the kid," which terrified him because he was the kid. Then followed, "the telephone burnt and got water after Suzy burnt." (Dr. "Where does water come from?") "I come from the show." (Dr. "You thought water and Walter were the same thing.") "My father used to take me across the river." (Dr. "And he called you Walter?") "And got drowned. I do not live on Springfield. Bad boys drink water. They do not drink milk. Good boys live on Springfield. I used to live on Springfield—Mississippi River."

A little later, Walter became much agitated over the telephone which had been "broken off" by the janitor—a confusion of the conversation and the instrument. He had always been afraid of one aunt, and now became irritated with his mother and began biting her. Then followed weeks of incessant questioning. Early in 1937, he had become frightened of movies and began to project his fears on his

brother, Sammy. He produced in drawing and speech, symbols which the doctor had difficulty in understanding. For example, he frequently drew things he called "rabbi" and a series of fifty such were interpreted by him "rabbi eating cock," in which "rabbi" meant "father" and "cock" was "kaka"—for feces. About this time, he began profuse spitting and confused "wash it up" and "wa shut up." His play with water now took the form of drowning anything in reach in the bathtub and pouring water into the family's beds.

During the succeeding year, Walter's behavior improved sufficiently for him to return to school and start to learn spelling. Although he frequently surprised his teacher by his intelligence, he more frequently failed to follow even her leading questions and seemed unable to master thoughts involving more than one sentence. He stood to attention, but always started late and would often smile and laugh to himself. *Masturbation began secretly and then publicly.* In April, 1940, he was excluded from school. His mental age, which had been above par when he was six, was now at seven, reported as four years, nine months. He failed in practically all tests involving numbers, reasoning, and so forth, and although he could draw a diamond to command, he could not complete the figure of a man lacking head, arms and one leg. On prompting, he drew legs all around it, even protruding from the head. What he learned was by rote and his writing had deteriorated.

We have in this patient gross defects in judgment and a lack of appropriate emotional response without any disorder of the sensorium at any time on record. These are Bleuler's three criteria. It is well to emphasize that it was the distortions in the realm of affection and consideration of others that his parents noted at the beginning of his "nonsense talk." This had paralogical traits, namely, the confusion of particulars with generals, of parts with wholes and of symbols with things symbolized, all escaping control by the real world about him. His thinking can scarcely be called more egocentric than belongs to his age, but it is autistic (cf Bychowsky¹⁰). His initial generalization of a child having been killed in an elevator in a store to all children and all elevators, and so his fear for himself in the store and the subsequent statements about the elevator and the kid, like his confusion of Walter and water in a child who could not spell, seem at first to belong to his age, but to think "I am water so I cannot be drowned," "I am water, water is being pounded in the radiator so I, the kid, and hence some other kid is being pounded in the radiator" is clearly paralogical (cf Domarus¹¹). We may put it thus: (1) I am water, (2) water is in the radiator, (3) I am in the radiator, whereas water is only his name, not himself. The obviously false conclusion, for he himself is not in the radiator, is escaped by (1) the "kid" is water

(2) water is in the radiator, (3) the "kid" is in the radiator and by not insisting that it be the same kid. In each case, the error really depends upon a failure to preserve the direction of symbolic reference—from the symbol to the thing symbolized. Water, the name, is not, but only denotes, water, the thing, and he himself, not water, is called "the kid." The extension of water to excretions and the puns thereon only extend the original confusion. The same holds for the rabbit and the cock.

Thus, throughout, there is a primary failure to distinguish between symbols which we can juggle at will in thought and the things meant by those symbols which are what they are and where they are regardless of our thoughts. This is the formal aspect of the defect of judgment and it clearly implies a lack of proper affect. No one to whom the world really matters normally, could make this type of mistake and, conversely, anyone who loses the direction of symbolic reference cannot be normally affected by the world. To account for the coherence observed in trains of thought, associationalistic psychology was forced to introduce the hypothesis of "task" or "Aufgabe," which is but a specification of interest or affection. Its loss may account for the so-called looseness of associations of ideas. For this reason, the resulting intrapsychic ataxia (cf. Stransky¹²) may depend upon some relatively localizable block in the pathways to the region determining that "set" (interest or task), instead of upon a diffuse alteration in the corticothalamic paths subserving the differentiation of our initially general abstractions. Thus, although the defect has a definable form, it does not point unambiguously to any one structure within the central nervous system.

In summary, in this paradigm of Bleuler's schizophrenia, we are confronted with a deterioration of judgment, paralogical in form, and characterized by that type of looseness of association of ideas that always accompanies aimlessness, which, itself, may be but a manifestation of the accompanying deterioration of affection and interest, all of which has occurred without any dreamlike or theater-like or fear-some or clouded state—i.e., with a clear sensorium.

Case II Not "Schizophrenia" by Bleuler's Third Criterion

Contrast this case with that of Melvin, eighteen, white, male, one of several healthy children of an outgoing household, an honor student and athlete just graduated from high school. On January 30, 1944, he failed to understand his family's instructions about the car, left it somewhere and could not remember whether he put it into the garage or left it on the street. The next day he was definitely dazed, hesitant in action, then undecided and irritable. That evening, when dressing

to go to a dance, he was confused, nervous and his face was pale and greasy. He returned at 4 A.M. with only a hazy memory of the night. His partner reported that, although he had had nothing to drink, he had seemed drunk and acted so strangely that she had not dared to leave him for a moment. From then, for a day and a night, he talked continuously and so confusedly that his family could not understand him. He grew fearful and hid when people came to the house lest they kill him or he, them. On the fourth day of his psychosis, he was seen by Dr. Rotman from whose pithy and detailed observations it is evident that Melvin had already become withdrawn and had begun to develop catatonic symptoms rapidly. On the fifth day he appeared so much engrossed in his own thoughts that a logical conversation could not be carried on and he already showed a tendency to refuse food. At this stage he thought that his father had lost his legs that he himself had land-mines in his trousers and he would unbutton them to make sure he had not lost his genitalia. On the sixth day he was admitted to Meyer House where he soon was mute, negativistic, grimacing, sweating profusely and exhibited wax flexibility, echopraxia, dilated pupils with poor reaction to light and, at times, sub-normal temperature. Lumbar puncture, blood sugar level and nonprotein nitrogen were negative. For five weeks he failed to recognize his parents. He carried his hand fearfully thinking it held a grenade. Twenty electric-shock treatments removed his catatonic symptoms and on March 22, 1944 he was discharged symptomatically recovered and with some insight.

Two days later his family called his condition to our attention. There were no delusions, hallucinations, or signs of catatonia, but the formerly warm hearted and loving boy was cool, unmannerly, estranged and selfish. There was no complete blocking but sentences were suddenly interrupted and then completed in a manner at variance with their beginnings. He was not aware that he was ill or that his character had altered. While in this condition of diminished affection and sympathy, or affectibility, but without clouding of consciousness, a series of laboratory tests at this institute was essentially normal. The white cell count was then 5000. On April 10, 1944, he became confused, clouded, puzzled and was admitted to the institute where he rapidly became disoriented, apprehensive and, then, thoroughly catatonic. The laboratory tests were repeated and were highly abnormal. The white blood count rose to 11,000, with a shift to the left, reaching 71 per cent polymorphonuclear leukocytes (Bruce¹⁸). During this phase his mutism and negativism made his ideas unavailable, but on recovery he explained that he had thought himself in London and the street noises were sounds of battle, at another time, that he was in a prison camp that kept changing into a German submarine—and we, his doctors, were its officers.

On April 27 he began to recover and by the first of May he was in

excellent condition Carbohydrate studies were again normal and the white cell count was 5000, with 60 per cent polymorphonuclear leukocytes On May 10 he was discharged with normal ideation, his old affectionate self and with full realization that he had been mentally ill. He has remained well to date

In summary, this paradigm of recoverable cases, resembling schizophrenia in two basic symptoms but not by the third criterion, exhibited five phases First, a sudden onset of clouding of the sensorium with fear-like apprehension and the flavor of a bad dream Second, catatonia, partially concealing hallucinations of being castrated and of holding a grenade in his hand and failure to recognize his family Third, a lucid period during which, despite clear sensorium and very slight ideational difficulty, there was loss of affectibility, and this phase showed normal carbohydrate regulation and blood count (Fig 34) Fourth, again a period of sudden clouding, apprehension and catatonia temporarily concealing disorientation for time, place and person—and this phase showed (a) positive Exton-Rose glucose reaction (i.e. up and again up as in diabetes),¹⁴ (b) a slow blood sugar curve, (c) resistance to insulin (i.e., delayed and diminished), and (d) abnormally large output of anti-insulinic factor in urine, as well as the leukocytosis described by Bruce (Fig 35) Fifth, recovery, a return to the premorbid state—"restitutio ad integrum"—with normal carbohydrate regulation and normal white cell count (Fig 36)

The complete recovery would have excluded the diagnosis of dementia praecox for Kraepelin and, by Bleuler's definition, should exclude schizophrenia

At this time, we do not wish to discuss other tests which were made and may be of localizing and qualifying value or to go into the treatment that may have initiated the final recovery, but it is necessary to point out that this disorder of carbohydrate regulation is not confined to this type of case In fact, a positive Exton-Rose reaction occurs in diabetes, pancreatic or pituitary, and in many so-called affective psychoses Infections produce insulin resistance and leukocytosis What is important is that the clouding of the sensorium was in this as in many another case, covariant with the alteration in carbohydrate metabolism

It is impossible to say whether this case, if untreated, would have remitted spontaneously or would have deteriorated, becoming "dementia praecox" But that even this curable or recoverable case went through the phase of clear sensorium with loss of affection, and some trouble in ideation engenders caution Nothing we have said should be taken to mean that the majority of the old cases of so-called schizo-

phrenia or dementia praecox may not have at one time exhibited a clouded sensorium. The convergence of pathologic processes renders

Fig 34—Phase 3 with unclouded sensorium, all tests normal E.R.T., Exton Rose, 2 dose per os 1 hour glucose tolerance test G.T.T., 0.15 gr per kilogram intravenous glucose tolerance test I.T.T., 0.1 units per kilogram intravenous insulin tolerance test A.I.F., average blood sugar of seven rats (circa 200 gm.) each injected intraperitoneally with one seventh of the total anti-insulinic factor obtainable from a specimen of 24 hour urine.

it likely that many, perhaps most, have done just that. Moreover there is no apparent reason why any case of true schizophrenia may not

subsequently show this clouding—certainly some old cases do. In fact, in 1938, Rumke¹⁵ of Amsterdam reported that a group of such cases treated with insulin or metrazol lost certain symptoms—"transitory" or "accidental" symptoms which frequently imply the clouding of the sensorium—but manifested a progressive shallowing or flattening and

Fig 35—Phase 4, oneiroid process, clouded sensorium, all tests pathological
Symbols as in Fig 34

a monotony of thought process, briefly, the old schizophrenia remained. One other point must be added to avoid possible misunderstanding. In our limited experience, the changes in carbohydrate metabolism indicated here occur in hebephrenic and paranoid pictures, when, and only when, there is a clouding of the sensorium.

The word sensorium is abbreviated from the Aristotelian term "sen-

sorium commune'—i.e., that place in which from diverse sensations of sight sound and touch, we form our ideas of position and motion and all other 'common sensibles'. That place must obviously be sought among the structures of the central nervous system. The structure is

Fig. 36.—Phase 5 restitutio ad integrum, all tests normal. Symbols as in Fig. 34

only defined for us by its function and it is alteration of that function which is the clouding of the sensorium. But all portions of the central nervous system are alike dependent upon the metabolism of glucose and oxygen. Deficit of either or undue acceleration or retardation of that metabolism must result in alterations of thresholds of

cells and consequently in the relation of their activity to external stimulation. Under given conditions, activity of particular cells implies a specific pattern of activity in cells afferent to them, and so ultimately in the receptors, and therefore a particular pattern in the world impinging upon us. Alteration of thresholds alters these implications so that the same pattern of activity in the cells of the more central structures may correspond to some other configuration of stimulation, and so yield a false inference as to the world. Clouding of the sensorium, disorientations, hallucinations, delusions, failures of perceptions, and a condition resembling dreams, shade into delirium as thresholds shift. If then, as in these cases, there is a gross disorder of carbohydrate regulation, including the presence of an excessive "anti-insulinic factor," it is not surprising to find that life assumes a dream-like quality as the sensorium becomes clouded. Thus, although we would not hazard a guess as to the cause of the metabolic disorder, we do regard the metabolic disorder as a factor in the clouding of the sensorium commune.

"ONEIROPHRENIA"

During the writing of this paper, it has become apparent to the authors that to dodge the circumlocution "a - disease - which - has - the - first - two - of - Bleuler's - criteria - but - has - a - clouding - of - the - sensorium - and - therefore - by - his - criterion - is - not - schizophrenia," a name for the disorder is wanted. Certainly "pseudo," "exogenous," "symptomatic," "-oform" and other negations of "true" schizophrenia are cumbersome and senseless or wrong. Moreover, there is current in psychiatric terminology an adjective introduced by Mayer-Gross¹⁶ to describe just such states in which dream and reality mingle. The word is *oneiroid*—made from the Greek *oneiros*, meaning dream. Beginning in 1588, it has made many compounds to be found in the Oxford English Dictionary. To give the picture its needed name having the right meaning with a minimum of innovation, we shall hereafter refer to it as *oneirophrenia*.

The diagnosis is to be made at the onset of the psychosis, not from the end product. Typically, that onset is acute, sometimes accompanied by alteration of body temperature and leukocytosis, generally manifesting defective judgment and distorted or diminished affect and invariably exhibiting some clouding of the sensorium ranging from mild disorders of perception, defective recollection or recognition, and confusion, to clear hallucinosis, disorientation and a condition verging on delirium. The prognosis is generally good for spontaneous remissions and for those induced by "Dauerschlaf," electroshock or metrazol. The pathophysiology includes at least a disorder of carbo-

hydrate regulation indicated by the pseudodiabetic reaction to the Exton-Rose test, and by the protracted sugar tolerance curves, the resistance to insulin and the presence of an excess of anti-insulinic factor in the urine.

SUMMARY

Aside from evidence of an increase in anti-insulinic factor in the urine of these patients, there is nothing essentially new in this paper,

SYNOPSIS

THE FEASIBILITY AND ADVANTAGES OF OUTPATIENT ELECTROSHOCK THERAPY FOR THE MENTALLY ILL

JOHN J. MADDEN, M.D.* AND JOSEPH A. LUHAN, M.D.†

Shock therapy introduced by Sakel¹ and Meduna² and modified by Cerletti and Bini³ has become an established method of therapy in psychiatric disorders. The manner in which improvement or recovery is brought about by the various shock therapies is a moot question, it would seem from experimental work carried out by various investigators that reversible metabolic alterations of a temporary character are induced in the central nervous system and these effects, when repeated, in some manner bring about alterations in structure-function relationship resulting in clinical improvement of the behavior disturbance called mental disease.

To many physicians uninitiated in its use shock therapy seems to be an exceptionally formidable procedure and its application confined within institutions devoted solely to the treatment of mental illness. The possibility of carrying out this treatment on an extramural basis came to our attention when several of our patients who were receiving treatment in a hospital for mental illness were required to leave for various reasons before their courses of treatment were completed. Since their improvement at this stage had not reached a satisfactory level, we were emboldened to attempt completion of treatment on an outpatient basis as an experimental venture. Our results were satisfactory and encouraging and prompted us to establish an outpatient facility for electroshock therapy at Loretto Hospital, a small general hospital affiliated with the Loyola University School of Medicine.

At first some difficulty was encountered in deciding what type of psychiatric disorder would be amenable to this therapy on an outpatient basis. Experience has shown that this procedure is particularly applicable in those cases of psychiatric disorder not accompanied by too blatant a behavior disturbance such as many depressive states of varied etiology, certain varieties of acute schizophrenic reactions,

From the Department of Neurology and Psychiatry, Loyola University School of Medicine, Chicago.

* Associate Professor and Chairman of the Department of Neurology and Psychiatry, Loyola University School of Medicine.

severe psychoneuroses, and the quasi-organic cases sometimes classified as psychosis with cerebral arteriosclerosis, accompanied by depression without significant memory loss or intellectual impairment.

Many of these patients could not be treated if inpatient hospitalization for the purpose of administration of shock therapy were insisted upon, mainly for economic reasons but also because of the objectionable connotation of confinement in a psychiatric section of a general hospital or in an institution devoted solely to the care of the mentally ill. One can frequently obtain much more cooperation from the patient himself if treatment is offered and he is allowed to remain at home or in his usual environment. In many patients, removal to a psychiatric hospital brings about a major adjustment difficulty which frequently aggravates the psychiatric disorder. As one of our depressed patients remarked, "I'm not nuts yet. Doctor, don't send me to a crazy hospital!" It would seem that the wider use of outpatient therapy would serve to relieve the present overcrowding in mental hospitals and the psychiatric facilities in general hospitals, and make therapy more easily available to many neglected borderline cases of mental illness sadly in need of help.

It has also been our experience that the existence of the outpatient facility in a general hospital oftentimes makes possible the satisfactory treatment of patients who exhibit a fairly acute behavior disturbance requiring hospitalization for a few days but responding to shock therapy with rapid amelioration of the acute symptoms, permitting the remainder of the treatment to be continued on an outpatient basis. This allows most general hospitals to serve as emergency psychiatric facilities provided that the directors or administrative officers are willing to cooperate in the minor adjustments necessary for the establishment of an outpatient shock therapy facility.

In our opinion, electroshock is preferable to the other two methods of shock therapy for use as an outpatient procedure. Insulin treatment is a much more cumbersome and dangerous method, requiring many hours per treatment and a selectively trained personnel to administer it. Metrazol, while simpler to use than insulin, must be introduced intravenously in varying dosage so that the desired convulsive effects are difficult to achieve, but the chief objection to its use is the terrifying apprehension developed in the patient by its administration so that cooperation for subsequent treatment becomes difficult or impossible to obtain. Frequently the resulting seizure is more severe and traumatizing than that obtained with electroshock.

TECHNIC AND APPARATUS

At the Loretto Hospital suitable arrangements were made in the physiotherapy department because convenient booths, enclosing treatment tables, and the necessary personnel were available. Help is frequently obtained from the general nursing and technician personnel of the hospital.

In our treatment plan we insist that a responsible friend or relative accompany the patient to the hospital. This serves a dual purpose: the relative can watch the patient during the post-treatment arousal period, thus relieving hospital personnel of this duty, and he acts as a protective companion for the perhaps dazed and slightly amnesic patient on his return home.

Preparation of the patient includes the interdiction of food or drink for a period of about four hours before treatment is given. The urinary bladder should be emptied just prior to treatment. These precautions prevent the possible aspiration of stomach contents in an unconscious patient, and soiling with urine which otherwise is occasionally encountered.

Permission for the treatment should be obtained in writing on a provided form from the patient or close relative before treatment is instituted. A general physical and neurologic examination is made of each patient and if any questionable cardiac abnormality exists an electrocardiogram is obtained before treatment is started. Further diagnostic studies, such as x-ray of the chest in suspected pulmonary disease, roentgenographic examination of the spine (in instances of suspected osteoarthritis or old spinal injury) or of the long bones (when severe osteoporosis is feared) may be indicated before treatment is begun.

The machine used is an Offner electroshock therapy apparatus which delivers a sine wave alternating 60 cycle current whose duration and strength may be varied by an electronic device. With this type of apparatus the treatment current intensity which is more important than the voltage, may be predetermined by the passage of a high frequency testing current which is not felt by the patient.⁴

The beds provided are ordinary wooden examining tables with overlying pads. Sandbags are placed underneath the patient to bring about hyperextension of the dorsal spine and tend to prevent the occurrence of vertebral fracture. However a surgical bed which can be broken or adjusted may be used. In such a bed the patient is placed with his head at the foot and the appliance ordinarily employed to flex the knees can be used in the place of a sandbag to hyperextend the dorsal spine.⁵

With the Offner apparatus the electrodes are attached to a perfo-

rated rubber band which encircles the head and holds them in a fronto-temporal position. An electrode jelly is applied to the skin and small cotton pads moistened with saline solution are interposed between the electrodes and skin surface. We have not found it necessary for the assistants to wear rubber gloves.

The patient is held by four assistants (Fig. 37). One of these, especially trained, inserts and maintains in place a gauze-covered rubber mouth protector, supports the jaw to prevent dislocation of the mandible, and supervises the restraint applied by the other three assistants. One assistant restrains the lower extremities while the other two

Fig. 37—Position of patient and assistants during treatment

exert pressure upon each shoulder girdle and upper extremity. The rubber mouth protector is simply a segment of rubber hose or a rubber door stop covered with gauze, and is used to prevent injury to the tongue and other soft tissues of the mouth during the biting movements which occur as part of the convulsive seizure. Removable artificial dentures are taken out of the mouth as a preliminary to the treatment. As preparations are being made the current is turned on in the machine to allow the tubes to become warm. The connecting terminal plugs from the machine are then inserted into the electrodes and the instrument is adjusted to deliver the predetermined current. In our experience, generalized convulsions (so-called grand mal seiz-

ures) can usually be produced with a current of 350 to 450 ma. and a time interval of 0.5 second. Occasionally in heavily sedated individuals, those with deep depression or older persons, the milli-ampereage may have to be increased as well as the time. In our experience at Ioretto Hospital thus far the most refractory patient has responded with generalized convulsions to a dose of 600 ma. for 0.7 second. In 75 per cent of our individual treatments, convulsions were achieved on the first attempt with 400 to 450 ma. acting for a period of 0.5 second.

It has been the experience of all workers in this field that petit mal-like responses (momentary loss of consciousness without convulsive movements) are therapeutically inefficient. Consequently, when a grand mal seizure fails to appear with a given dose, a second shock of higher milli-ampereage or longer time, or both, is given after respirations have returned to a normal rhythm, usually within three minutes. If a convulsive response is not obtained in three trials, we believe that further treatment attempts should be deferred for twenty-four hours. Once the convulsive threshold dose for a given patient is determined, grand mal-like responses may be obtained in subsequent treatments administered to that patient in most instances with this same amount of current.

The electrically induced grand mal-like attack resembles an idiopathic epileptic seizure in many of its dramatic aspects.⁶ When the circuit is closed instantaneous loss of consciousness ensues, followed almost at once or in a few seconds by the convulsive phenomena which are usually more severe than in the epileptic seizure and follow a motor pattern somewhat different from that seen in the usual case of idiopathic grand mal seizure. From a practical standpoint, however, one must bear in mind that the initial manifestation of the electrically induced fit is unusually severe. The pupils become dilated and do not react to light during and for some time after the convulsion, and the eyeballs usually deviate conjugately upwards or to one side. After a temporary pallor the face becomes flushed and, as the period of apnea may be prolonged for many seconds, considerable cyanosis can develop. Retrograde amnesia for the convulsion regularly occurs.

The assistants must be on the alert to restrain the patient adequately during this startling, lightning-like initial lunge because at this time injuries most frequently occur. The assistants should be prepared for the suddenness and violence of this reaction and cautioned to exert full restraint in anticipation of circuit closure. Occasionally the onset of clonic convulsions is delayed for as long as fifteen seconds after the initial loss of consciousness ("delayed grand mal reaction") so

that restraining measures should not be relaxed if an immediate convulsion does not ensue with closure of the electrical circuit

As soon as convulsive movements cease the patient is quickly turned on his right side and a pillow placed beneath the head for support. This position is maintained until regular respiration reappears and marked salivation no longer occurs, usually in three to five minutes

As consciousness is being regained, acute restlessness with clouding of consciousness occurs in a considerable proportion of cases and rarely amounts to an acute furor reaction. For this reason we deem it advisable to apply restraining straps or bands across the chest and over the lower extremities above the knees as soon as the patient is replaced on his back. This can be done by means of folded sheets which are passed beneath the table around the patient and tied

Depending on how rapidly and completely consciousness is regained, the patient is allowed to go home with his companion within one-half to one and a-half hours after the treatment. Both the patient and his companion are advised that he should return home to rest for the remainder of the day and, if headache occurs, to take 5 or 10 grains of aspirin

Treatments are ordinarily given three times a week. Before treatment is begun the relatives are informed that an increasing degree of memory disturbance may and probably will supervene as therapy is continued. They are reassured that this is a temporary disability, probably of therapeutic value, and will subside within a comparatively short time, usually within three to four weeks of termination of treatment. Soreness of the limbs and back is a frequent sequel of treatment, but this is ordinarily of no serious significance and has been produced by muscular and soft tissue strain

CONTRAINDICATIONS

The usual type of patient selected for treatment from a psychiatric standpoint was outlined above. However, in spite of these well marked psychiatric indications, certain accompanying disabilities may contraindicate this type of treatment or its use on an outpatient basis. As a contraindication to this form of therapy certain somatic disturbances assume paramount importance: acute febrile illness, advanced age, severe cardiovascular disease, bone and joint disorders predisposing to fracture or which would be aggravated by violent muscular movement, and latent tuberculosis which experience with related metrazol therapy shows may be stirred into activity

In spite of the seeming rigors of the treatment, in our experience many individuals with evidence of a moderate degree of cardiovas-

cular disease may be safely and beneficially treated by this method. In fact, we have treated some patients with advanced cardiovascular disease with striking benefit, especially when the psychotic manifestations seemed to be aggravating the physical disability. To illustrate this point the following case history is presented.

Mr. W. S., a white male 54 years of age, a professor of engineering in a technical college, had been under care for a year and a half for cardiovascular disease accompanied by fatigue, anorexia, headaches and an inability to carry on efficiently at his usual work. Three months before admission for electroshock therapy he went to Florida for a "rest." Here he found the situation not conducive to rest and attempted to return home. Transportation facilities were overloaded and he was forced to wait six weeks before suitable train accommodations could be obtained. During this period of delay the patient became increasingly uneasy and restless, and said that he and his wife would never get home. He felt that he was being watched by everyone and emanated a disagreeable odor because of the dissolution of his internal organs caused by excessive cigarette smoking. Upon arriving home these symptoms became more severe. He feared to leave the house, saying the neighbors would shoot him since they felt he was a neighborhood menace.

Examination revealed an emaciated male appearing older than 54 years. Palpable evidence of arteriosclerosis was present in the accessible vessels. There was also noted a vascular hypertension of 230/100 with moderate cardiac enlargement and electrocardiographic findings of coronary sclerosis with considerable myocardial damage and probable old infarction. The patient was markedly agitated, slept little and ate poorly, and continuously voiced the delusional ideas mentioned above. Electroshock therapy was deferred for about a week because of the seemingly great risk involved, and during this period the blood pressure remained at a high level (225/90 to 250/115). After a conference with his wife and a close friend, both of whom felt something must be done to forestall a state of exhaustion which seemed imminent, treatment was begun.

A grand mal seizure was obtained with 450 ma at 0.5 second. Respirations began promptly and after a temporary period of irregularity lasting three or four minutes, cardiac action resumed a normal rhythm. Blood pressure reading immediately after muscular movement subsided was over 300 systolic, which was the highest reading obtainable with the sphygmomanometer, diastolic pressure was 185.

Treatment was continued three times weekly for a series of seven treatments. At this point all psychiatric symptoms had disappeared and the patient resumed his former normal personality pattern. He has now been free from symptoms of his mental disorder for five months.

that restraining measures should not be relaxed if an immediate convulsion does not ensue with closure of the electrical circuit

As soon as convulsive movements cease the patient is quickly turned on his right side and a pillow placed beneath the head for support. This position is maintained until regular respiration reappears and marked salivation no longer occurs, usually in three to five minutes.

As consciousness is being regained, acute restlessness with clouding of consciousness occurs in a considerable proportion of cases and rarely amounts to an acute furor reaction. For this reason we deem it advisable to apply restraining straps or bands across the chest and over the lower extremities above the knees as soon as the patient is replaced on his back. This can be done by means of folded sheets which are passed beneath the table around the patient and tied.

Depending on how rapidly and completely consciousness is regained, the patient is allowed to go home with his companion within one-half to one and a-half hours after the treatment. Both the patient and his companion are advised that he should return home to rest for the remainder of the day and, if headache occurs, to take 5 or 10 grains of aspirin.

Treatments are ordinarily given three times a week. Before treatment is begun the relatives are informed that an increasing degree of memory disturbance may and probably will supervene as therapy is continued. They are reassured that this is a temporary disability, probably of therapeutic value, and will subside within a comparatively short time, usually within three to four weeks of termination of treatment. Soreness of the limbs and back is a frequent sequel of treatment, but this is ordinarily of no serious significance and has been produced by muscular and soft tissue strain.

CONTRAINDICATIONS

The usual type of patient selected for treatment from a psychiatric standpoint was outlined above. However, in spite of these well marked psychiatric indications, certain accompanying disabilities may contraindicate this type of treatment or its use on an outpatient basis. As a contraindication to this form of therapy certain somatic disturbances assume paramount importance: acute febrile illness, advanced age, severe cardiovascular disease, bone and joint disorders predisposing to fracture or which would be aggravated by violent muscular movement, and latent tuberculosis which experience with related metrazol therapy shows may be stirred into activity.

In spite of the seeming rigors of the treatment, in our experience many individuals with evidence of a moderate degree of cardiovas

cular disease may be safely and beneficially treated by this method. In fact, we have treated some patients with advanced cardiovascular disease with striking benefit, especially when the psychotic manifestations seemed to be aggravating the physical disability. To illustrate this point the following case history is presented.

Mr W S, a white male 54 years of age, a professor of engineering in a technical college, had been under care for a year and a half for cardiovascular disease accompanied by fatigue, anorexia, headaches and an inability to carry on efficiently at his usual work. Three months before admission for electroshock therapy he went to Florida for a "rest." Here he found the situation not conducive to rest and attempted to return home. Transportation facilities were overloaded and he was forced to wait six weeks before suitable train accommodations could be obtained. During this period of delay the patient became increasingly uneasy and restless, and said that he and his wife would never get home. He felt that he was being watched by everyone and emanated a disagreeable odor because of the dissolution of his internal organs caused by excessive cigarette smoking. Upon arriving home these symptoms became more severe. He feared to leave the house, saying the neighbors would shoot him since they felt he was a neighborhood menace.

Examination revealed an emaciated male appearing older than 54 years. Palpable evidence of arteriosclerosis was present in the accessible vessels. There was also noted a vascular hypertension of 230/100 with moderate cardiac enlargement and electrocardiographic findings of coronary sclerosis with considerable myocardial damage and probable old infarction. The patient was markedly agitated, slept little and ate poorly, and continuously voiced the *delusional ideas* mentioned above. Electroshock therapy was deferred for about a week because of the seemingly great risk involved, and during this period the blood pressure remained at a high level (225/90 to 250/115). After a conference with his wife and a close friend, both of whom felt something must be done to forestall a state of exhaustion which seemed imminent, treatment was begun.

A grand mal seizure was obtained with 450 ma. at 0.5 second. Respirations began promptly and after a temporary period of irregularity lasting three or four minutes, cardiac action resumed a normal rhythm. Blood pressure reading immediately after muscular movement subsided was over 300 systolic, which was the highest reading obtainable with the sphygmomanometer, diastolic pressure was 185.

Treatment was continued three times weekly for a series of seven treatments. At this point all psychiatric symptoms had disappeared and the patient resumed his former normal personality pattern. He has now been free from symptoms of his mental disorder for five months.

The psychiatric contraindications include behavior disturbances of such intensity that institutionalization is required. Depressed patients with marked suicidal tendencies should not be trusted to the inexperienced supervision of relatives and friends and should, therefore, not be treated as outpatients. Organic brain disease such as general paresis, brain tumor, Huntington's chorea, parkinsonian states productive of behavior disturbances, senile dementia, Alzheimer's disease, and so forth, are unresponsive and treatment by this method is often dangerous.⁷ Chronic, deteriorated schizophrenics rarely respond to treatment, therefore, while no contraindication exists, neither is there an indication for treatment. Occasionally when a patient with chronic schizophrenia who is able to remain at home under the supervision of relatives becomes acutely yet mildly disturbed, the acute behavior disturbance may be ameliorated by a course of shock therapy.

DANGERS AND COMPLICATIONS

The dangers and complications of indiscriminate electroshock therapy are considerable. Fractures occurred frequently with the use of metrazol, less often with electroshock, but in our experience are not a prohibitive hazard when suitable precautions are taken. Before hyperextension of the spine and adequate manual restraint were routinely employed, the incidence of fractures with metrazol convulsive therapy was high, with 43 per cent of one series of patients⁸ developing single or multiple fractures of the bodies of the thoracic vertebrae. In later reports, fractures of other bones (humerus, scapula, femur, mandible) were described. With electroshock treatment given under similar conditions as metrazol, the proportion of fractures encountered was significantly smaller. Vertebral fractures complicating electroshock therapy can be largely eliminated by the use of hyperextension of the spine and proper restraint. Worthing and Kalinowsky⁹ found that re-examination of eight patients with severe multiple spinal fractures incurred two years previously disclosed no orthopedic or neurologic evidence of progressive pathology, and expressed the opinion that fractures are no contraindication against shock treatment since they can largely be avoided and, if they do occur, have no clinical importance. We have not searched for vertebral fractures with the x-ray, should they occur, as in the past with the use of metrazol, little disability is caused and no special treatment is required. Considerable backache may develop after treatment on the basis of soft tissue strains without fracture. In our outpatient experience we have encountered no fractures of long bones. On several occasions

dislocation of the mandible occurred which was reduced before consciousness was regained and after the convulsion had ceased

In the attempt to prevent the occurrence of fractures by "softening" the convulsion, *curare* was introduced by Bennett,¹⁰ first in conjunction with metrazol and later with electrically induced convulsions. Curarization is not without danger, and the use of *curare* (Intocostin) in conjunction with electroshock is not advised unless the physician stands ready to combat prolonged apnea and suffocation by means of artificial respiration, the administration of prostigmine as an antidote and the insertion of an airway. We had not encountered any serious reactions with its occasional use on inpatients until two of four extramural patients treated with *curare* at Loretto Hospital developed alarming apnea, cyanosis and obstructive dyspnea. In one of these patients consciousness had already returned when the airway had to be inserted, and the patient refused further treatment because of recollection of this terrifying experience. We speculated that another indication for the use of *curare* might be found in hypertensive subjects to prevent or diminish severe transient rise of blood pressure occurring with the induced convulsion, but experience did not bear this out. Woolley¹¹ has shown that marked variations in blood pressure occur, often with violent rises in hypertensive subjects, in *curare* protected metrazol and electric shock. We feel, therefore, that *curare* should not be used in conjunction with outpatient electroshock treatment.

Fatalities associated with electroshock probably occur at the rate of about one in 1000 cases.¹² A number of these deaths took place when *curare* was used. In most instances death is caused by circulatory failure, acute cardiac dilatation in a previously diseased heart may result from the tremendous muscular exertion of the convulsion or circulatory failure may occur without obvious heart disease from disturbance of cardioregulatory and vasomotor centers. In our personal inpatient and outpatient experience with electroshock we have thus far not encountered a fatality.

In our experience no significant aggravation of the mental illness has taken place as the result of treatment. Each patient has exhibited a temporary memory disturbance, which may approach mild confusion as treatment progresses. If relatives and associates are forewarned to expect these symptoms much apprehension and anxiety is allayed. Occasionally severe transient excitement may follow treatment. This is a disturbing complication because of the pandemonium created and the possibility of injury to patient or personnel. In such patients it is our practice to terminate outpatient treatment at once.

We do not recommend electroshock therapy as a routine office procedure, in spite of the reported experiences of others¹³ However, in certain so-called office clinics the facilities available may approach a hospital environment and be readily adaptable to the procedure.

In our experience, psychotherapy beyond that of instruction and simple reassurance seemingly has played no rôle It is possible that more subtle psychotherapeutic elements, such as the dramatics of the treatment, physician-patient relationship or other intangibles, may be operative We feel that formal and intensive psychotherapy during treatment is almost precluded because of the rapidly developing amnesia which accompanies this mode of therapy In this series we have avoided all psychotherapeutic efforts in order to evaluate the effects of electroshock treatment per se

RESULTS IN SEVENTY-FIVE CASES

This report does not attempt to evaluate the general results of electroshock therapy This has been and continues to be the subject of a number of studies¹⁴ based on larger groups of patients We have given about 600 individual treatments during the past eleven months to seventy-five outpatients at Loretto Hospital The ages of these patients ranged from 16 to 68, with a median age of about 35 years The ratio of women to men was almost two to one Sixty-five patients have either completed their course of treatment or are no longer under treatment Of these, four received only one treatment and four more, only two Omitting these cases, the remaining fifty-seven patients received an average of seven treatments apiece The largest number of treatments administered in any one case was nineteen The period of observation since cessation of treatment varied from two to eleven months, and therefore it is too early to evaluate long term results In the fifty-seven cases the diagnosis and immediate results were as follows

Involuntional depressions and psychoses, 17 cases, results, 13 good, 4 fair

Reactive depressions, 8 cases, results, 6 good, 1 fair, 1 poor

Manic-depressive depressions, 4 cases, results, 3 good, 1 fair

Marked psychoneuroses, usually with depressive features, 13 cases, results, 3 good, 8 fair, 2 poor

Schizophrenic psychoses and reactions, 12 cases, results, 3 good, 6 fair, 3 poor

Cerebral arteriosclerosis with depression, 2 cases, results, both good

Psychosis with mental deficiency, 1 case, result, good

Thus in depressive states particularly involutional, manic-depressive and so called reactive depressions, good immediate results were obtained in over three-quarters of the patients treated, whereas in psychoneuroses, particularly with some depressive features but in which psychosomatic complaints and phobias dominated the picture, and in schizophrenic reactions and psychoses, only about a fourth of the patients underwent marked improvement following treatment. No benefit whatsoever accrued from this therapy in about 11 per cent of the whole group of patients.

The case history previously cited illustrates an immediate therapeutic result classified as "good." As an example of a "fair" result the following case may be cited.

A 37 year old married woman who previously made a satisfactory social adjustment, gradually developed symptoms of mental illness, becoming overt two months before she came under psychiatric care. She had gone to work in a "defense" factory ostensibly to defray the expense of a college education for her 17½ year old son. After some months she became infatuated with the foreman at her place of work, this was clearly an autistic love affair, and took on serious proportions only after the son, to whom she was strongly attached entered the Army and shortly thereafter became engaged to be married without his mother's knowledge or consent. In effect the boy had jilted his mother for a sweetheart after the former had made sacrifices to enable him to become well educated and make a mark in the world. The patient spoke freely of her infatuation for this foreman and entertained the idea that he reciprocated her affections but was afraid to admit it. As a result of conflict over this infatuation she left her job two months prior to treatment, expressed increasing dislike for her husband, and finally left her home to stay with a relative.

She related to the examiner how for some months she had been watched and followed by mysterious persons who would take flash-light pictures of her, since she heard the click of the camera and saw the bursts of light. Her husband, a janitor, appeared very much devoted to his wife but apparently had not been aware that she was suffering from a serious mental illness.

It was explained to the patient that she had undergone such nervous shocks that she was in no condition to make major decisions concerning separation or divorce from her husband and was finally prevailed upon to enter Loretto Hospital as an inpatient for a course of shock treatment. The diagnosis was paranoid schizophrenic psychosis. She remained in the hospital for a week receiving four treatments, and continued treatment as an outpatient for three more treatments. Her condition improved, she became reconciled with her husband, has resumed her former household responsibilities, gave approval for her

son's marriage, and no longer felt that she was being followed and photographed. She no longer spoke of her infatuation for the foreman. Her husband considers her well, but the patient has no insight into her behavior and shows some affective leveling. She has continued to make a satisfactory adjustment for the past ten months.

SUMMARY

We have discussed the evolution and practical operation of an outpatient electroshock facility in a small general hospital. The advantages of such outpatient treatment are mainly economic, and make therapy available to many neglected borderline cases of mental illness. The selection of patients for treatment, the dangers and complications of this method and the results in a preliminary series of cases are reported.

INSOMNIA

MEYER SOLOMON, M D *

THIS discussion will be limited to insomnia in adults, with special emphasis on ambulatory office patients rather than home-confined, hospital or sanitarium patients

Although etymologically insomnia, or sleeplessness, means lack of sleep from any cause or causes, ordinarily it is used synonymously with hypsomnia or lessening of the duration or depth of sleep, or both, acute or chronic, from any cause or combination of causes, psychologic or nonpsychologic. Since the depth and duration of sleep vary considerably from one individual to another and from one season to another, and since, unless the behavior is such as to attract the attention of or to annoy others, there is often no good objective criterion of insomnia, it is usually, insofar as ambulatory office patients are concerned, a subjective complaint unless supported by confirmatory observation of members of the family or others

The complainant's story and interpretation may or may not be correct, since it may vary according to his well-being and how much significance he attaches to getting a certain number of hours of sleep of a quality satisfactory to himself. As Klingman,¹ quoted by Kleitman,² has so neatly put it "Those who sleep eight hours and believe that they need ten consider themselves to be suffering just as much from insomnia as others who cannot get more than four or five hours of sleep but who would be satisfied with six or seven." It should be added, nevertheless, that under certain circumstances some persons who get ten hours as their average sleep are not in optimum condition on two hours less. But such decrease in their preferred amount of sleep can usually be corrected by reorganizing their daily routine or conditions of living by establishing an earlier hour of retiring, correcting the physical arrangement in the bedroom, and investigating such causes of morning awakening as noise or light.

It is therefore important to check the patient's complaint of insomnia carefully, with full details as given by the patient and, if possible, by others in the home, before accepting at its face value the truth of the general complaint as given by the patient. For example,

From the Department of Nervous and Mental Diseases, Northwestern University Medical School, Chicago

* Associate in Nervous and Mental Diseases, Northwestern University Medical School, Chairman, Department of Neuropsychiatry, Mount Sinai Hospital

a patient complained to me that, among other annoyances she had suffered from poor sleep for two years past. On careful inquiry it was learned that this amounted to nothing more than partially awakening in the middle of the night for a few minutes or so and immediately dropping off to sleep again and sleeping soundly until about 8 o'clock in the morning. Furthermore, she had lost no weight and had none of the other clinical effects of real sleeplessness over a two year period.

CLASSIFICATION OF INSOMNIA

Insomnia is unquestionably one of the most common complaints in medical practice. Although there are many classifications of the condition, such as age, degree of completeness, clinical diagnosis, and whether acute or chronic, I shall refer here in particular to classification according to cause and to time of incidence.

Based on the time of incidence there are three types of insomnia (1) Difficulty or delay in falling asleep, known as *initial* or *predormitional insomnia*. This is the most common type and results especially from habit, fear, worry and anxiety states, with the ability to sleep late in the morning. Laird⁷ goes so far as to claim that it occurs in three fourths of the population. (2) Intermittent, broken, restless sleep, which varies almost directly with age, and Laird⁷ believes that it occurs in about 40 per cent of adult men. This type of insomnia is commonly associated with unpleasant dreams and nightmares, and in middle-aged persons is frequently accompanied by digestive disturbances. (3) Early morning awakening, so-called *terminal insomnia*, with difficulty in returning to sleep. This is normal with advancing age, is common in arteriosclerosis and hypertension and, I agree with Pollock,⁸ Muncie⁹ and many others, is especially present in mental depression.

It has been found that most people wake up spontaneously during the second half of the night but fall asleep again, and that when one has had "enough" sleep, one awakens more and more frequently and finds it more and more difficult to fall asleep again until finally one remains awake.² When this final stage is reached by 3 or 4 or 5 o'clock in the morning instead of the usual hour of awakening (6 or 7 or 8 o'clock or so), the condition is called terminal insomnia. When this occurs in elderly persons, who ordinarily need less sleep than formerly but who go to bed at the usual if not an earlier hour and are worried if they do not sleep to as late an hour as previously or as late as younger people do, one need have no concern. Also, it is not merely a question of how early one awakens but how early one re-

tures, how many hours of sleep one has had and how light or heavy a daily program one follows

Combinations of the above three types of insomnia may occur. Occasionally there is a reversal of the sleep rhythm with wakefulness by night and sleep by day, as in some cases of epidemic encephalitis and in cerebral arteriosclerosis with other manifestations of senility.

CAUSES OF INSOMNIA

Insomnia is a symptom of some underlying cause or causes. There are three main groups of causes, as follows:

(1) *Purely external*, such as extremes of heat or cold, light (especially early morning sun), noise (especially early morning traffic), uncomfortable bedding, crowding, and so forth.

(2) *Physical diseases and toxic causes*. This covers a large number of conditions, including pain or severe discomfort from injury or disease of any kind, organic disease not especially accompanied by pain, as in tuberculosis, arteriosclerosis, thyrotoxicosis, heart disease and hypertension, organic brain disease, tinnitus aurium, or post-traumatic, or from arthritis, neuritis and the like, cerebral excitement from endogenous toxic states such as infection or uremia, as well as from exogenous toxins such as the excessive use of coffee, tea or alcohol especially in the latter part of the day, gastro-intestinal disturbances with discomfort from dyspepsia, indiscretions in diet, hunger, hypoglycemia, and so forth.

(3) *Psychological causes*. These are the most common causes of insomnia and comprise the whole range of mental and emotional factors, the psychoneuroses (fatigue or neurasthenic, anxiety, hysterical and obsessive-compulsive states) and psychoses (especially depressed, excited, confusional and schizophrenic states), worry about and especially fear of insomnia, of the possibly serious effects of sleeplessness, of insanity and of incurability. Insomnia which is not traceable to physical disease or to some definite physiological or external origin, is most apt to be associated with anxiety about something and it is our job to find out just what that something is.

It is clear that insomnia is always a definite indication that something about the patient needs investigation since it may be the end product of a multitude of possible causes and, like cough or pain or dyspnea, is only a symptom. Difficulty in sleeping dependent upon residual excitement from the day is not uncommon in sensitive, excitable, worried individuals. Some such individuals have a certain degree of recurrent insomnia of many years' duration.

Psychogenic insomnia with sleeplessness as the only complaint at

the original consultation is often complex and requires careful study, diagnosis and management. In other instances it is simple in origin and management from the very beginning.

It will not be possible to discuss the characteristics and treatment of insomnia in special clinical conditions such as delirious, excited and similar states. This aspect will be found in the various clinical texts on psychiatry or psychological medicine.

CLINICAL EFFECTS OF LOSS OF SLEEP

For an authoritative discussion of sleep which, unfortunately, I have no space to present, I urge you to consult the very splendid book by Kleitman² on *Sleep and Wakefulness*. He conducted experiments on partial deprivation of sleep with continued muscular activity so that the effects were due partly to lack of sleep and partly to muscular fatigue. In his standard procedure there was a waking period of sixty-two to sixty-five hours of staying awake until late in the evening of the third day of sleeplessness. He himself remained awake on various occasions to 100 hours and with the aid of benzedrine sulfate as long as 180 hours. He found, in general, no deviations from the normal range in the vegetative functions (heart rate, blood pressure, body temperature, basal metabolism, appetite, composition of the blood and urine), while the red blood cells and hemoglobin percentage showed variable results but with no general tendency to oligocythemia.

In studying the effects on the nervous system, Kleitman employed two classes of tests with the following results: (1) Tests in which effort is not a determining factor (knee jerks, pupillary light response, cutaneous sensibility to faradic current, touch and pain, visual acuity, brain potentials, electrical skin resistance) showed, as with vegetative functions, no consistent variation for the group as a whole for all tests but one, namely, sensitiveness to pain, with cutaneous sensitivity to touch unchanged but to pain a progressive increase (lower thresholds). (2) Tests in which effort is a determining factor showed in general a decreased performance ability during the period of sleeplessness. Although mental and muscular performance in various tests can be maintained at normal levels if the tests are of short duration, sustained effort is impossible. The most outstanding and significant findings in all studies on lack of sleep were found to be increased sensitivity to pain, impairment of the disposition with hyperirritability and irascibility, a tendency to day-dreaming, hallucinations and other similar signs. All of these point to fatigue of higher levels of the cerebral cortex, which are in constant operation during the period of

wakefulness and are responsible for the critical analysis of incoming impulses and the establishment of adequate responses in the light of the person's or animal's experience Kleitman found in humans itching or slight burning sensitiveness of the eyelids, and mild mannered persons became ill tempered under continued efforts to keep them awake Thus, the sleepy individual can make a short lasting effort but cannot sustain it.

Many experiments have shown that animals die from lack of sleep ⁸ Menace's puppies after four to six days, Tarozzi's three dogs after nine, thirteen and seventeen days, although Pieron's twenty dogs were alive after from 30 to 505 hours and Okazaki's after fourteen to seventy-seven days, of Kleitman's twelve puppies kept awake from two to seven days two died without awakening after being permitted to sleep In experimental animals which died or were killed after a period of insomnia, various brain and other nervous system changes have been reported

Kleitman concludes ⁴ "From observations made on persons undergoing experimental insomnia it can be stated with assurance that no immediate untoward developments need be feared from the loss of a night's sleep, whether it be partial or complete Prolonged, continuous wakefulness, however, even if undergone voluntarily, may cause temporary mental deterioration"

Insomnia in clinical practice is a more complicated matter Here the patient is worried about his sleeplessness, he knows that it is not voluntary or merely experimental, and it may continue not merely for days but for weeks and months Varying with the cause, we commonly note increased fatigue, lack of concentration, deficiencies of memory, inability to perform effective mental work, impairment of muscular coordination (especially for more delicate movements), anorexia, irritability of temper, loss of weight, head and bodily paresthesias, restless and agitated pacing of the floor, and general physical and mental instability ¹⁰ Weight loss, especially in depressed patients, due to insomnia, anorexia and other factors, may be as much as 20 to 50 pounds

Craig¹¹ is right when he says "Some persons are much more intolerant of deficient sleep than are others, indeed, some individuals will become definitely insane within a few days if sleep is not obtained" Popov⁵ reports such a case, with complete recovery after the patient was allowed to sleep

I also agree with Minogue¹² of Australia who found that insomnia from whatever cause led to rapid mental and physical exhaustion, usually with headaches, especially a "tight band around the head" as

if "the head were bursting" If long continued, the patients become desperate, restless, apprehensive, many are haunted by the fear of insanity, some may later become suicidal, especially if living alone, with no relatives or friends to console them, if too religious or if elderly Minogue quite correctly concludes "Suicide is the end result of a large number of factors, both physical and psychological Whatever its cause, it is generally preceded by a period of insomnia with its concomitant symptoms and signs It is imperative for us to realize the risk of suicide in such patients and also that the patient requires urgent and immediate treatment If appropriate treatment is given, I am convinced that many a suicide can be prevented, a fact well known to all psychiatrists But unless we, as a profession, realize that sleepless, depressed and worried patients are prone to suicide, and that such patients can be very successfully treated by modern psychiatric methods, there seems to be little hope of appreciably reducing the suicide rate in Australia" What is true of Australia is likewise true of the United States.

In considering the dangers of real insomnia, one must appreciate the possibility of a vicious circle with insomnia aggravating the nervous and mental condition, and vice versa I have summarized¹³ the situation briefly in a previous discussion in the following words "It is not merely the direct results of lack of sleep but its indirect and psychological results which are of serious import. The patient's hours of wakefulness at night, with everyone else sleeping and all quiet, may seem to him very much longer than they in fact are. It is also during such periods at night that his rushing thoughts, emotionalism, anxiety, worries and fears take possession of him in more unrestrained fashion Then come his worries over the real or imagined dangers of insomnia. Being more unstable because of insomnia, he is inclined the following day to be more in the grip of his anxieties and fears His worry about the lack of sleep leads to an excessive interest in whether or not he will sleep well He may have actual despair from his sleeplessness Fear of the night, of insomnia and of bed time may become predominant. Fear of insanity may result from insomnia primarily or be exaggerated by it. Although insomnia is only one cause of the fear of insomnia in psychoneurotics (and psychotics) it is an important cause. Continued sleeplessness may lead to a feeling of lack of self-confidence and self-control"

In all cases of persistent, prolonged insomnia the patient should be studied carefully to determine whether or not a real mental depression is not the actual clinical condition present, and, if so, it should be treated as such, with, if severe enough and indicated, hospitaliza-

tion and so-called electroshock therapy, in selected cases estrogen therapy^{15 16} in the female and androgen therapy¹⁷ in the male have apparently been of value in true involutional melancholia

GENERAL MANAGEMENT OF INSOMNIA

In all cases a careful sequential history of the onset and development to date is essential. This should include its degree, duration, effects, probable cause of onset, factors responsible for its continuation, and the patient's attitude toward his condition. His other complaints should be gone into sufficiently fully. Review the patient's daily program—his time of arising, routine of the day, hour of retiring, the amount and character of his sleep before and since the onset of his insomnia.

A personality estimate and determination of the mental condition, with decision as to the existence or absence of a psychoneurosis or psychosis and the approximate clinical diagnosis can usually be made during the first extended consultation.

Take the complaint of insomnia as seriously as you do (or should) any other symptom.

At the outset a full physical examination should be made with definite exclusion of obvious causes (such as pain, dyspnea, pruritus), diseases of the gastrointestinal, circulatory, respiratory or excretory systems, hypertension, organic neurologic diseases and alcoholic toxic states. Whatever laboratory tests are really necessary should not be omitted. By this time you should have a more definite opinion concerning the patient and his complaint.

Each case is an individual affair. No fixed rules can be laid down.

Unless the patient is willing to put himself under your care, to see you frequently enough and to permit proper study and supervision, it is better to give merely general advice, outline the situation and not prescribe hypnotics except for two or three nights and then not to be refilled. Explain your reasons to the patient.

All psychoneurotic patients with insomnia, except of the slightest degree, are much better sleeping alone. All clocks are generally best removed. A dark, quiet, properly ventilated room is desirable.

Each individual has his favorite, preferred choice of bedspring, mattress, bedding, pillow arrangement, ventilation and posture in bed. If there is increased blood pressure, have the patient try using no pillow.

If there is sensitiveness to cold, a warm bed—even with hot water bottles—is in order. If cold feet while in bed are a source of discomfort, help may be found in a hot foot bath at bedtime, or hot water

bag to the feet, being sure to avoid burns, or the patient may wear woolen socks to bed.

If the patient is hungry at bedtime, milk or warm soup with crackers a half hour before retiring should be soporific. If awakening occurs from hunger, a glass of milk and crackers may be taken at the time of awakening.

If there is overuse of coffee, tea or alcohol, reduce the amount consumed during the latter part of the day or after lunch, especially at or near bedtime. The effect of coffee and tea varies from one person to another.

If there is flatulent distention of the stomach or intestines, try one-half glass of water with 10 to 15 grains (0.65 to 1 gm) of sodium bicarbonate at bedtime.

For disturbing symptoms in medical or surgical conditions, such as cough or dyspnea, relief as necessary is in order. Some patients are helped, others made worse, by a glass of hot whiskey or water, by reading, or by attempts at muscle relaxation at bedtime. Gentle massage, especially of the spinal muscles, just before the usual sleeping time is apt to be valuable, especially in neurasthenics and bed patients.

To exclude the early morning light, opaque window shades (dark green shades instead of or in addition to yellow, tan or white ones) should be drawn low at bedtime. For sleeping by day, the use of an opaque screen about two feet from the window is helpful. Avoid having the light fall directly on the head.

Sedative hydrotherapy may be employed in several ways: as prolonged (one quarter to one-half hour) warm (96° F) bath, cold wet pack for three-quarters to one hour, or, in excited states, neutral tub baths for two or three hours or continuously, especially with an ice cap to the head. The last is always, and the second is usually, a hospital procedure.

Suggestion, assurance, diversion, distraction, release of anxiety and tension are occasionally of service as conditioning processes to induce sleep. Drinking or eating or even a warm bath, muscular relaxation, various psychological procedures such as listening to one's breathing, prayer, autosuggestion of Coué, naming categories following the alphabet, and so on.

If sleeplessness follows a period of unusually concentrated or prolonged mental work, a short vacation with plenty of rest and sleep should be advised, often at the onset, with the addition of mild hypnotic medication.

I know that many of the above suggestions cannot be carried out in certain patients owing to limitations of living quarters, hours of

employment and financial situation, but no symptom demands such varied therapeutics

As Kleitman⁶ concludes "Insomnia, in the sense of hypsomnia, is nearly always traceable to some disturbing factor, capable of keeping the cortical centers, or the wakefulness center in the hypothalamus, directly in a state of prolonged activity. The therapeutics of insomnia consist in the removal of the disturbing factors and, if that fails, in the use of depressing drugs"

In the majority of cases no physical cause can be found for the insomnia and the patient needs a combination of a common sense exploration of his mental and emotional problems with psychological management, a survey of his daily program of activity, and the rational use of hypnotic drugs

PSYCHOLOGICAL ASPECTS AND PSYCHOTHERAPY

In considering psychogenic insomnia, emotional conflict is so important that its consideration is really an introduction to the problem of psychoneuroses and so-called functional psychoses. Thus, the management of the patient goes step by step with the treatment of the symptom of sleeplessness. This means an investigation of the patient's personal problems, his state of health, his daily program, domestic (marital and family), financial, occupational, social, recreational, sexual, religious, and ethical-moral adjustments

The attitude of the physician must very definitely be one which inspires confidence. The physician must have and show confidence in his own ability to help the patient recover and in the patient's ability to regain his equilibrium

In the treatment of a disease associated with insomnia, one must remember that in continued pain with prolonged insomnia, especially in unstable individuals, eventual psychoneurosis or even psychosis may result. In like manner organic disease of any sort may clear up and insomnia continue

Discuss the past anxieties which led to or the present anxieties which maintain the insomnia. With time, interest, sympathy, patience and understanding in the very first interview or the first few interviews, the patient will confess his anxieties, medical and nonmedical. Some can, others cannot, be settled by discussion. If you cannot remove the anxiety responsible for the sleeplessness, at least reassure the patient as much as possible. Use explanation, suggestion and readjustment of his daily program, attitudes and ambitions, as the case may be.

If intensive personality study is indicated, I do not favor adhering to any one school of psychological thought, Freudian or otherwise,

but study each patient individually, letting the quips fall where they may

I do not find any real basis to the current systems of dream interpretation and their supposed invariable importance and value in unearthing the causes of the disorder

Hypnosis is ordinarily of no, little or temporary value and it may not be possible to use it in sleeplessness in office patients

PHARMACOTHERAPY THE USE OF HYPNOTIC DRUGS

Owing to space limitation I shall confine my discussion to the pros and cons of using hypnotics in general and to technic and precautions in their use

The chemistry, characteristics, dosage and methods of administration of the various drugs can be found elsewhere, as in the presentations by Weiss,¹⁸ Feiling,¹⁹ Fantus,²⁰ Winans,²¹ Dercum,²² Diethelm,²³ Ross,²⁴ Crichton-Miller²⁵ and Grabfield.²⁶ For special attention to the barbituric acid group I refer you to Weiss¹⁸ and the special report of the *Journal of the American Medical Association*²⁷ Goodman and Gilman²⁸ give a comprehensive discussion

The Case For and Against the Use of Hypnotics—Sleeplessness due to pain and other discomfort requires necessary symptomatic relief, even morphine or codeine. Hyoscine is used exclusively in selected cases in psychiatric hospital practice. Bromides are rarely effective in insomnia of real consequence. Chloral and paraldehyde, not used as frequently now as formerly, are in my opinion for hospital and sanitarium rather than home use in ambulatory office patients

By hypnotics I refer more particularly to the drugs of the barbituric acid group such as barbital, veronal, medinal, sodium amytal, ipral, nembutal, seconal, "delvinal" sodium and many others, and much less to the so-called sedative group, bromides, chloral, paraldehyde, but not at all to the so-called euphorotics (alcohol, opium, morphine, heroin, cocaine) I agree with others that with a change of dosage a so-called sedative may produce hypnosis or narcosis.

Surely there can be no scientific objection to the desirability or necessity of medication for actually disturbing symptoms of emotional origin, as for instance the temporary use of hypnotics for psychogenic insomnia while the patient is being studied and treated causatively. And yet there is a surprising disagreement in attitude and policy on this important clinical problem. This is especially so in the case of insomnia accompanying the psychoneuroses. As I¹⁸ have said elsewhere, among the large number of psychotherapists and psychopathologists who are in direct opposition or do not openly advocate or even mention the occasional necessary use of hypnotics in the treat-

ment of insomnia in the psychoneuroses, I found such names as Dubois, Janet, Freud, Jung, Adler, McDougall, Prince, Dejerine and Gauckler. Yet we find that Dejerine and Gauckler²⁰ admit that the patient with insomnia of phobic origin often clings to his fear of insomnia so strongly that the bad habits which he has formed are frequently kept up in spite of all psychotherapeutic efforts.

As a consequence of the many arguments against the use of hypnotics by men of the highest standing in psychopathology, and of newspaper items emphasizing the dangers of habit formation or referring to their employment for suicidal purposes, many physicians fear or apologize for prescribing hypnotics under any circumstances. This in my opinion is illogical, unscientific and unfair to patients, the medical profession and the public in general. The main arguments against their use, and answers to these arguments, have been given by me¹⁴ elsewhere and are herewith summarized.

1 The use of hypnotics is not causal treatment, but palliative, however, symptomatic treatment is employed elsewhere in medicine.

2 There is danger of toxic effects, but their avoidance, as with other drugs, is merely a question of technic and precautions.

3 Self-medication may ensue, but with proper precautions this should not result.

4 Their use is a temporary and not permanent help or solution, but this applies to all palliative therapy.

5 It is a resort to an artificial crutch, but so are many other procedures in practice.

6 It is a line of least resistance, but it need not be so abused.

7 Other necessary treatment may be neglected by physician and/or patient, but it should not be.

8 It gives the patient the wrong idea of the causes and of the fundamental importance of the psychotherapeutic aid required, but it does not if properly handled.

9 There is danger of drug addiction.

10 The drug ordered may be used for suicidal purposes.

The last two arguments will be answered immediately. I fully endorse the views of Craig⁹ who spoke from much experience when he said "As a profession we are unduly timid of giving hypnotics and in consequence the public, as a whole, objects to them. Brought up as I was in the same attitude, long experience has taught me the folly of such an outlook. The chief objection, I gather, is the fear of inducing a habit. Once more experience has taught me to be much more afraid of the effects of sleeplessness than of any danger of producing an addiction, a danger which is almost negligible. Let those persons who

are constantly talking about addiction produce the evidence upon which they base their statements'

Although the suicidal use of the drug ordered is apt to occur in the psychoses and alcoholism, precautions in the method of prescribing should prevent this. Suicidally inclined patients, not psychoneurotic, have many sources (newspaper items and drug stores) of information concerning hypnotics. Suicidal use is especially apt to take place in worried depressions. But an important aggravant of this possibility is the unrelieved, prolonged, marked insomnia present in such psychotic states. Psychoneurotic patients are notoriously not inclined to suicide.

Too many physicians make the mistake of misdiagnosing real mental depressions, even of the worried or agitated type, as psychoneuroses, and in such depressions the need of sufficient sleep is absolutely essential and fundamentally basic in treatment. In fact, practically all truly depressed patients with insomnia are in need of the aid of hypnotic medication since they are especially resistant to all methods of psychotherapy. Such depressed patients should, if their condition is pronounced enough, be hospitalized, hypnotics used as required, necessary precautions against suicide observed, and so-called electroshock therapy instituted when indicated. Furthermore, prolonged, severe insomnia may lead to depression and suicidal thoughts and attempts.

One of the common characteristics of depression, if not slight or mild, as in excited and other states, is the inability to secure a sufficient amount of sleep with moderate doses of hypnotics.

Craig* was certainly fully justified when he insisted that 'As with every other disorder, the sooner we treat sleeplessness the more quickly we shall be able to correct it, and, what is most important of all, sleeplessness quickly relieved leaves no terrors behind it compared with prolonged insomnia. The physicians who are most likely to produce a drug habit are those who have permitted their patients to become terrified by the experience through which they have passed.

"In the case of hypnotics for insomnia, it is generally true that it is not the drug but the lack of confidence in the ability to sleep without it which may become a habit, with the result that they are reluctant to break away from the means which have afforded them relief."

It is our duty to see to it that patients are satisfied and relieved if at all possible by nondangerous methods adapted to the particular case. Our personal preferences should not be made rigid practices.

We surely are not justified in dismissing patients suffering from insomnia by merely telling them that it does not matter whether they

sleep or not, or that they will sleep if they will not worry about it, or to forget it.

Even if he is exaggerating his degree of insomnia, the patient must be satisfied that he is sleeping soundly and sufficiently, the general condition of the patient should always be the real guide. If the patient is in a condition in which he cannot be satisfied by explanation or by other measures, hypnotics should be temporarily used.

If you can easily and quickly produce sleep, you have a much better chance of getting a psychological hold on the patient and of increasing his confidence in himself. A period of sleep promptly given helps rapidly to break up the habit of sleeplessness, to diminish or to eliminate the other bad physical and psychological effects of insufficient sleep, and to put the patient in a psychological condition more susceptible to psychotherapy and physiotherapy. At the same time, fear of the medication given him which is so often present and deep rooted should be removed. As a matter of truth, if hypnotics are not used for insomnia, one can never be sure that other measures will produce sleep. Therefore, without the employment of hypnotics, one cannot give any definite promise of sleep on any particular night. But with medication one is fortified and can assure the patient that with a sufficient dosage and with one or the other of the hypnotics or some combination of them, sleep can positively be obtained. Furthermore, if you continue to assure a patient that he will sleep without hypnotics but his sleeplessness continues, you are gradually losing the confidence of your patient.

In fact, as Ross³⁰ says, it is certain one can be just as unscientific in withholding hypnotics as in giving them when it is not indicated.

Technic and Precautions in Using Hypnotics—I shall here enumerate many practical "do's and don'ts."

Deal with your patient insofar as possible on the principle of "open covenants openly arrived at."

Explain to the patient that you are using hypnotics temporarily, that you will study and treat his general condition and that hypnotics will be gradually omitted.

As many patients fear the use of hypnotics, after explaining your plan to the patient, get his views and attitude. Assure him that if he takes only what medication you order and remains under your medical supervision and sees you as frequently as you wish, he need fear neither the "dope habit" nor toxic effects.

If occasionally the patient at first prefers not to take hypnotics temporarily even when so requested by you, he will generally agree to do so after he gains more confidence in you.

All prescriptions for hypnotics or sedatives should have a "non repetatur" or "Do not refill" order

Do not prescribe hypnotic tablets or capsules by the bottle. Order only enough to last until the next visit.

Do not tell the patient to take hypnotics as he needs or wishes. And do not have him renew his prescription on his own initiative or renew the prescription for hypnotics routinely by telephone. Such methods lead to self-medication with its possible dangers.

If the patient is suicidal, and this can usually be determined at the first visit, do not give the prescription or medication directly to him but to someone else (relative, nurse) who will have control of it. Such suicidal patients, of course, really need hospitalization.

Do not promise positive sleep the first night but promise that sufficient sleep can be obtained shortly with proper dosage and combination of hypnotics.

Give a large enough dose at once to insure sleep, if possible, the very first night of treatment.

Explain in advance some of the possible undesirable results (such as drunken feeling) the morning after taking the drug and until the dose is adjusted.

After a sufficient number of good nights of sleep the usual patient readily agrees to gradual reduction of dosage until it can be omitted altogether. Sometimes at this stage if he prefers, one dose of the drug can be placed within reach of the patient to be used, if he wishes or really needs it without rising. This may give him the degree of assurance which will lead to peaceful sleep.

In office practice it is best not to continue using hypnotics for more than two to three weeks or so without attempting to reduce the dose gradually.

The hypnotic should preferably be varied as the patient improves or fails to get results.

If permanent relief depends upon a knowledge of the cause of the insomnia and the patient refuses to cooperate in finding out the cause, one may refuse to give hypnotics until he changes his attitude.

A supply for only two or three days at a time should be ordered as a rule. In selected cases during the convalescent phase this may be somewhat extended.

It is well to have at least a telephone report daily for the first few days.

See the patient, if at all possible, at least two or three times a week in the first week, the frequency thereafter varies with each case.

If the patient cannot be seen frequently enough to check up on the

progress, the diagnosis, possible toxic effects, the advisability of increasing or decreasing the dose or best time of administration or of changing the medication, refuse further to treat the patient or to assume any responsibility

In the case of the average office patient I give the prescription directly to the patient or relative without fear of misuse since I have examined the patient sufficiently, have arrived at a tentative diagnosis, have made reasonably sure that he is not suicidal, have given an explanation and the plan of procedure and have had an understanding with the patient. This does not apply to depressed patients, especially if more than slightly depressed, and particularly if suspected of being suicidal, in which case, unless hospitalization seems definitely indicated, the hypnotic is under the control of someone else in the home.

If preferred, you may dispense the hypnotic yourself or have special arrangements with the druggist to give the hypnotic without the patient knowing its name.

It is much better to know a few selected hypnotics well than to know too many too little.

Use hypnotics judiciously combined with causal therapy, including psychotherapy plus any palliative physiotherapy advisable.

When, from the history and condition of the patient, real help is needed for obtaining essential sleep, hypnotics should be used not merely as a last resort and half-heartedly but promptly from the very first visit and wholeheartedly—with the practical suggestions as to technic and precautions enumerated above.

SO-CALLED ELECTROSHOCK AND INSULIN SHOCK THERAPY IN PSYCHOSES WITH INSOMNIA

Where insomnia is part of a psychosis, we find that, as the psychosis is improving, sleep without medication is one of the earliest signs of such improvement. This applies to the use of so-called insulin shock and electroshock treatment, which has almost universally displaced metrazol.

In depressions, including agitated depressions, in which pronounced and prolonged insomnia is common, so-called electroshock treatment produces remarkable results in a large proportion of patients, with a clearing up of the sleeplessness in many cases in a truly unbelievable manner. The patient soon gets along without drugs.

It cannot be too often emphasized that many cases of depression are wrongly diagnosed psychoneurosis and so improperly treated. Although mild depressions may be treated on an ambulatory, home-office, extramural basis, others, especially the more pronounced and

more particularly the agitated types with marked insomnia and suicidal thoughts or tendencies, need immediate hospitalization

Schizophrenic patients, especially early, may be greatly helped or may recover by so-called electroshock and/or insulin shock therapy plus psychological management

INSANITY AND THE CRIMINAL

WILLIAM H HAINES, M D * AND HARRY R HOFFMAN, M D †

MANY years ago Boswell¹ wrote, "Patriotism is the last refuge of the scoundrel." This could be paraphrased into, "Insanity is the last refuge of the criminal." Insanity vs responsibility has always played a rôle as a defense in criminal procedure, as many years ago courts decided that criminals found to be insane could not be held responsible for their crimes. One must remember when insanity is used as a defense it is used as an alibi. It is claimed the mind was not there, and therefore one should not be held responsible for his actions.

HISTORICAL BACKGROUND

As early as 1625 Coke² wrote, "In criminal causes, as felony, the act and wrong of a madman shall not be imputed to him, as he is without his mind or discretion." In 1675 Sir Matthew Hale² wrote, "If a lunatic during his lunacy a man distraint by force of disease, kills himself, no felony. A man that is *non compos mentis* kills another this is no felony, the same for a lunatic during his lunacy." A lunatic was supposed to have lucid intervals during which he was *compos mentis*.

Hale also discussed partial insanity and total insanity, but admitted it was very difficult to determine the dividing line between the two. In regard to partial insanity he wrote, "This is the condition of many, especially melancholic persons, who generally discover their defects in excessive fears or griefs and yet are not wholly destitute of reason, and thus partial insanity seems not to excuse them in the commission of any offense for its matter capital." And he suggests that "such a person is laboring under melancholy distempers, hath as yet, as great understanding as ordinarily a child of fourteen years hath, is such a person as can be guilty of treason or felony." In 1723³ it was ruled that a man cannot be acquitted on the grounds of insanity unless he is totally deprived of understanding and memory and does not know what he is doing any "more than an infant, or a brute or a wild beast."

In 1800 James Hadfield,² a soldier, shot at King George III. At the time of the trial evidence was presented that he had been discharged from the army on the grounds of insanity, that he suffered from

* Director Behavior Clinic, Criminal Court of Cook County, Illinois, 1941-

† Director, Behavior Clinic, Criminal Court of Cook County, Illinois, 1931-1941 at present, State Alienist.

attacks of maniacal frenzy and had labored under various delusions. He also said that he knew perfectly that his life was forfeited, that he was tired of life and regretted nothing but the fate of the woman who was his wife and would be his wife a few days longer, he supposed. He calmly stated that his plan was to get rid of his life by other means than suicide, that he did not intend to take the life of the King for he knew that the attempt only would answer the purpose. The Attorney-General said, in summing up his case before the jury, that according to law, "If a man be completely deranged so that he knows not what he does, if he be so lost to all sense that he cannot distinguish good from evil, and cannot judge the consequences of his action, then the mercy of the law said that he cannot be guilty of any crime because the will which, to a certain extent is the essence of every crime, is wanting. Persons of very weak understanding had committed crimes and had been punished in consequence for them though their understandings were considerably below the ordinary level because juries had decided that they had sufficient understanding to discriminate between right or wrong."

The defense attorney described Hadfield to the jury and said "He imagined that he had constant intercourse with the Almighty Author of all things, that this world was coming to a conclusion, and that, like our Blessed Savior, he was to sacrifice himself for its salvation, and so obstinately did this morbid image continue, that you will be convinced that he went into the theatre to perform, as he imagined, that blessed sacrifice, and because he would not be guilty of suicide, though called upon by the imperious will of heaven he wished that, by the appearance of the crime, his life might be taken away from him by others." The attorney referred to the words of Coke, "He that wholly loseth his memory and understanding, a prisoner, in order to be acquitted on the ground of insanity, must be a man that is totally deprived of his understanding and memory." He added, "No such madman ever existed in the world." He further said, "When a man is laboring under a delusion existing at the time of committal of the offence, and the act was done under its influence, then he cannot be considered as guilty of any crime."

The presiding judge is reported to have said, "With regard to the law, as it is laid down, there can be no doubt on earth. To be sure, if a man is in a deranged state of mind at the time, he is not criminally answerable for his acts, but the material part of the case is whether, at the very time when the acts were committed the man's mind was sane. His sanity must be made out to the satisfaction of a moral man meeting the case with a fortitude of mind, knowing he has an arduous duty to discharge." The jury found that Hadfield was in-

sane at the time he committed the act although he knew at the time of the shooting he was firing a loaded pistol at the King, and that it was an act punishable by law

In 1812 *John Bellingham*² was tried for murder for shooting a pistol in the House of Commons. He had years before been legally arrested for attempting to leave Russia while a criminal suit was instituted against him. Later he was acquitted, but he felt that the British Government should compensate him for his injuries and oppression. He had made many overtures to British officials and felt that he had not been sympathetically received. At the shooting he stood unnoticed and when someone asked "Where is the villain that fired?" he stepped up to the man and coolly said, "I am the unfortunate man. It is a private injury. I know what I have done. It was a denial of justice on the part of the government." To a friend he added, "The crime was perfectly inevitable, there was no wrong at all in doing it, he could not help that." Bellingham was sentenced to death and executed on the seventh day after the murder. The Lord Chief Justice, in summing up, said "There is a species of insanity where people take particular fancies into their heads, who were perfectly sane and sound of mind upon all other subjects, but that is not a species of insanity which can excuse any person who has committed a crime, unless it so affects his mind at a particular period when he commits the crime, as to disable him from distinguishing between good and evil, or to judge of the consequences of his actions. The question is whether you—the jury—are satisfied that he—the prisoner—had a sufficient degree of capacity to distinguish between good and evil, and to know that he was committing a crime when he committed this act, in that case you will find him guilty."

Also in 1812 *Bowler*² was tried for shooting and injuring a Burrowes with a loaded blunderbuss. Bowler was tried, found guilty and executed. At the trial he was proved to have suffered from epilepsy. He had previously threatened Burrowes and had said, "Damn that Burrowes, I will burrow him before long. I will be the death of him if I am hanged for it the next minute, so long as my name is Bowler." The judge instructed the jury "It is for you—the jury—to determine whether the prisoner when he committed the offence with which he stands charged was, or was not, incapable of distinguishing right from wrong, or whether he was under the influence of any delusion with respect to the prosecutor which rendered his mind at the moment insensible of the nature of the act he was about to commit, since, in that case, he would not be legally responsible for his conduct. On

the other hand, provided you should be of the opinion that when he committed the offence he was capable of distinguishing right from wrong and was not under the influence of such a delusion as disabled him from distinguishing that he was doing a wrong act, in that case he is answerable to the justice of his country and guilty in the eye of the law "

In 1840 *Oxford*² was tried for shooting at Queen Victoria and was acquitted on the grounds of insanity. He was a mental defective and medical testimony for the defense revealed "A deficient understanding an occasional appearance of acuteness but a total inability to reason, a singular insensibility as regards the affections. An apparent incapacity to comprehend moral obligations to distinguish right from wrong. An absolute insensibility to the heinousness of his offence and to the peril of his situation, a total indifference to the consequence of the trial, acquittal will give him no particular pleasure, and he seems unable to comprehend the alternative of his condemnation and execution, his offence is like that of other imbeciles who set fire to buildings, etc., without motive, except a vague pleasure in mischief, he appears unable to conceive anything of future responsibility." In summing up the Lord Chief Justice is reported to have told the jury, "If a man were the agent of a controlling disease which he could not at all resist, he was not then held to be a guilty party, and he would be entitled to have an acquittal upon that ground. Every case must stand to some extent on its own base. That man charged as a criminal is not responsible for the act who is, in the language of our law, 'non compos mentis'—that is, unable to distinguish between right and wrong. Every sort of insanity, and every mode of proving it, must have reference to the particular object with which it was laid before the court. Here the object was to show that at the time of committing the act the prisoner was not able to distinguish right from wrong."

In 1843 *McNaghten*² was tried for willful murder and was found by a jury to be insane. Evidence showed that McNaghten with premeditation shot his victim in the back without any altercation or any provocation on the victim's part. McNaghten, two years before the shooting, had asked his father to put a stop to a persecution that was raised against him. He thought spies were following him and had left Glasgow to avoid the spies, then went to England, and later to France. No sooner had he landed in France than the spies saw him. At the trial many prominent people testified to McNaghten's beliefs. Among the witnesses were a sheriff, a member of Parliament, a minister of the church, the provost of Glasgow and the Commissioner of Police of Glasgow.

Medical testimony by Dr E. J. Monro revealed that McNaghten said That he was persecuted by a system or crew at Glasgow, Edinburgh, Liverpool, London and Boulogne, that this crew followed him wherever he went, that he had no peace of mind, that he was sure it would kill him, that in Glasgow he observed people in the streets pointing at him and speaking of him They said, "That is the man, he is a murderer and the worst of characters." Wherever he went, in town or in country, on sea or on shore he was watched and followed

everything was done by signs he was represented to be under a delusion, and on coming out of the courthouse he had seen a man frowning at him with a bundle of straws under his arms, and the straw denoted that he should lie upon straw in an asylum In answer to questions from defending counsel, witness said "He frequently knew a person insane upon one point exhibit great clearness upon others not associated with his delusions an insane person may commit an act similar to the one with which the prisoner is charged and yet be aware of the consequences of such an act." And in cross-examination the doctor said, when asked if insanity may exist with a moral perception of right and wrong "Yes it is very common" And in re-examination he gave it as his opinion that he had not the slightest doubt the prisoner's moral perceptions were impaired, and added "I think a delusion of this nature carries a man quite away I mean that his mind was so absorbed by the contemplation of this fancied wrong that he did not distinguish between right and wrong"

Counsel for the defence, as reported by The Times, said "He did not bring this forward as a case of complete, but of partial insanity

He trusted he had satisfied the jury by the authorities he had quoted, that there existed such a disease as partial insanity or homicidal monomania, in which the unhappy patient, acting under the influence of instinct, was led on by delusion to commit crime for which morally he could not be held responsible"

The Lord Chief Justice in summing up, is reported to have said "The point which at last will be submitted to you will be whether or not on the whole of the evidence you have heard you are satisfied that at the time the act was committed, for the commission of which the prisoner stands charged, he had not that competent use of his understanding as not to know what he was doing with respect to the act itself—a wicked and wrong thing—whether he knew it was a wicked and wrong thing he had done, or that he was not sensible at the time he committed this act that it was contrary to the laws of God and man. Undoubtedly if he were not so sensible he is not a person so responsible." And later he adds "If upon balancing evidence in your minds you should think the prisoner a person capable of distinguishing right from wrong, with respect to the act with which he stands

charged, he is then a responsible agent, and liable to the penalties imposed upon those who commit the crime of which he is accused "

Following the trial of McNaghten, the House of Lords put five questions of procedure to the judges because there was a wide difference both in meaning and in words in their description of the law. From their answers is formed our legal concept of insanity of today, namely "He is punishable according to the crime committed if he knew at the time of committing such a crime that he was acting contrary to law " Because the questions^{2, 4} are not noted in the textbooks of psychiatry, we are quoting them in full

QUESTION 1—"What is the law respecting alleged crimes committed by persons afflicted with insane delusions in respect of one or more particular subjects or persons, as for instance, whether, at the time of the commission of the alleged crime the accused knew he was acting contrary to law, but did the act complained of with a view, under the influence of insane delusion, of redressing or revenging some supposed grievance or injury, or of producing some supposed public benefit?"

Answer 1—"Assuming that your lordships' inquiries are confined to those persons who labour under such partial delusion only, and are not in other respects insane, we are of opinion that notwithstanding the party accused did the act complained of with a view, under the influence of insane delusion, of redressing or revenging some supposed grievance or injury, or of producing some public benefit, he is nevertheless punishable according to the nature of the crime committed if he knew at the time of committing such a crime, that he was acting contrary to law, by which expression we understand your lordships to mean the law of the land "

QUESTION 2—"What are the proper questions to be submitted to the jury when a person afflicted with insane delusion respecting one or more particular subjects or persons is charged with the commission of a crime (murder, for instance) and insanity is set up as a defence?"

QUESTION 3—"In what terms ought the question to be left to the jury as to the prisoner's state of mind at the time when the act was committed?"

Answers 2 and 3—"As these two questions appear to us to be more conveniently answered together, we have to submit our opinion to be that jurors ought to be told, in all cases, that every man is presumed to be sane, and to possess a sufficient degree of reason to be responsible for his crimes, until the contrary be proved to their satisfaction, and that to establish a defence on the ground of insanity it must be clearly proved that at the time of the commit-

ting of the act the accused party was labouring under such a defect of reason, from disease of the mind, as not to know the nature and quality of the act he was doing, or, if he did know it, that he did not know he was doing what was wrong. The mode of putting the latter part of the question to the jury on these occasions has generally been whether the accused, at the time of doing the act, knew the difference between right and wrong, which mode, though rarely, if ever, leading to any mistake with the jury, is not, we conceive, so accurate when put generally and in the abstract, as when put with reference to the party's knowledge of right and wrong in respect to the very act with which he is charged. If the questions were to be put as to the knowledge of the accused solely and exclusively with reference to the law of the land, it might lead to confound the jury by inducing them to believe that an actual knowledge of the law of the land was essential in order to lead to conviction, whereas the law is administered upon the principle that everyone must be taken conclusively to know it without proof that he does know it. If the accused was conscious that the act was one which he ought not to do, and if the act was at the same time contrary to the law of the land, he is punishable, and the usual course therefore has been to leave the question to the jury whether the accused had a sufficient degree of reason to know he was doing an act that was wrong, and this course we think is correct accompanied with such observations and explanations as the circumstances of each particular case may require."

QUESTION 4—"If a person under an insane delusion as to existing facts commits an offence in consequence thereof is he thereby excused?"

Answer 4—"The answer must of course depend on the nature of the delusion, but making the same assumption as we did before—namely, that he labours under such partial delusion only, and is not in other respects insane—we think he must be considered in the same situation as to responsibility as if the facts with respect to which the delusion exists were real. For example, if under the influence of his delusion he supposes another man to be in the act of attempting to take away his life, he kills that man as he supposes in self-defence he would be exempt from punishment. If his delusion was that the deceased had inflicted a serious injury to his character and fortune and he killed him in revenge for such supposed injury, he would be liable to punishment."

QUESTION 5—"Can a medical man, conversant with the disease of insanity, who never saw the prisoner previously to his trial, but who was present during the whole trial and the examination of all the witnesses, be asked his opinion as to the state of the prisoner's mind at the time of the commission of the alleged crime, or his opinion

whether the prisoner was conscious at the time of doing the act, that he was acting contrary to law, or whether he was labouring under any and what delusions?"

Answer 5 — "We think the medical man under the circumstances supposed, cannot in strictness be asked his opinion in the terms stated, because each of those questions involves the determination of the truth of the facts deposed to, which it is for the jury to decide, and the questions are not mere questions upon a matter of science, in which case such evidence is admissible. But where the facts are admitted, or not disputed, and the question becomes substantially one of science only, it may be convenient to allow the question to be put in that general form, though the same cannot be insisted on as a matter of right."

It will be noted that the answer to Question 5 forbids the admissibility of direct questioning of the psychiatrist on the prisoner's mental condition at the time of the crime, so it is customary to put the question of insanity before the jury by means of a hypothetical question. In this question all the favorable evidence is introduced and then a hypothetical person is discussed. The jury and all in court know that it is the prisoner being discussed but he is not called by name. In many cases this is the only way that the defense can prove that a prisoner was insane at the commission of the crime. Dr William A. White¹⁶ has called the hypothetical question a monstrosity.

BEHAVIOR CLINIC ORGANIZATION AND FUNCTIONS

In order to eliminate the so-called battle of the alienists in Chicago, in which the state and defense hired many psychiatrists, each testifying for the side by which they were retained, a committee of judges of the Criminal Court of Cook County and the Institute of Medicine in Chicago suggested the formation of a psychiatric clinic whose function would be to render an impartial psychiatric opinion to the court. From this suggestion the County Commissioners of Cook County created the Behavior Clinic of the Criminal Court in 1931. This is a branch of the Cook County Bureau of Public Welfare.

In the Behavior Clinic the examination of the criminal is made only on an order of a trial judge and consists of a physical examination, psychiatric examination, psychometric examination and a social history. A summary is prepared with conclusions and is sent to the court in triplicate so the judge may in turn give a copy to the State's Attorney and the defense attorney at his discretion.

This report to the court is limited by court order to (1) the physical findings, (2) the pertinent social history with especial attention

to any previous mental disease in the patient or his family (no mention can be made of previous penal institutions or previous criminal record), (3) the mental examination, (4) psychometric examination if pertinent. The conclusion is to state, for Criminal Court cases, whether or not active mental disease is present and the type of such disease if present, whether the individual knows the nature of his charge, and whether he can cooperate with his counsel.

In practically every case in which the Behavior Clinic is asked to make an examination, the attorneys, the patient's parents, the clergy, or some other interested person contacts the office and describes in detail the mental condition of the patient either in years past, at the time of the commission of the offense, or at the present time, suggesting that because of this erratic behavior he was not responsible for the consequence of his acts.

In addition, if the case under examination is "sensational," we receive telephone calls or letters in which the individual caller explains his theory of why the defendant committed the crime. Frequently these calls accuse the psychiatrists at the Behavior Clinic of being on the side of the state or of the defense and not giving an *unpartisan* decision. The majority of the calls are received when the Behavior Clinic reports that an individual is insane and the defendant is committed to a hospital for the criminally insane. The callers feel that *justice is thwarted* and do not realize that the defendant will have to stand trial upon his restoration of sanity.

Frequently the Behavior Clinic is asked by the court to examine a prisoner who refuses to cooperate for an examination. This refusal on the part of a defendant to permit examination is usually on the advice of his counsel, especially if the defense intends to employ its own psychiatrists. The law does not force a defendant to submit to an examination, so that his refusal to cooperate with the court psychiatrist constitutes the highest degree of cooperation with his own counsel. When refusal to cooperate is reported to the court, it can be inferred that the defendant is sane. Occasionally a defendant may not cooperate with the state's attorney when his statement is taken and may give the state's attorney irrelevant answers to suggest insanity or simply indifference. However, he tries to cooperate with the court psychiatrist. One exmillionaire of the prohibition era responded flippantly and irrelevantly to each question the state's attorney asked him prior to his trial. At the psychiatric examination he told of his vast estates with golf courses private chauffeur for each of his children, and his ability to "buy" state's attorneys at 'a dime a dozen in the old days.' However, he added, "There is just one man I'm afraid of and it's the

'bug' doctor If you find me insane, I'll be sent to an institution for the criminally insane and it will be months before I can put the machinery in order to get out" With his own lawyer and the psychiatrist he cooperated fully

LEGAL CONCEPTIONS OF INSANITY

If at any time the question of insanity is raised by either the defense or prosecution and it is called to the attention of the court, it is mandatory that a jury be impaneled and a civil trial be held to determine the defendant's mental condition Under our law, a man is always considered sane until proved insane If a defense attorney permits his client to enter a plea on arraignment for the charge, it is the same as admitting that he is competent and therefore sane He, however, can always use insanity at the time of commission of the act as a defense To do this, he must present testimony to that effect during the trial and then by means of a hypothetical question have the alienist give his opinion of the mental state of a hypothetical person at the time of commission of the crime

One must bear in mind that the legal conception of sanity differs at times from the medical interpretation of mental disease Insanity is a legal term applied to the individual's responsibility for his behavior His lack of responsibility may be due to mental disease or mental defectiveness This condition of insanity may be inherent in the individual or it may be acquired With this in mind, we can easily postulate a number of variations in the state of an individual's sanity before and during a criminal trial, namely He may be (1) insane at the commission of the crime and have recovered from his insanity at the time of the trial, (2) insane at the commission of the crime and still insane at the time of the trial, (3) sane at the commission of the crime and insane at the beginning of the trial, (4) insane during the progress of the trial, (5) sane during the trial and insane before pronouncement of sentence, (6) sane at the pronouncement of sentence and insane before execution of the sentence

The Supreme Court in Illinois in separate decisions have defined the tests necessary to declare a defendant insane at the different stages of his trial These are

At Commission of a Crime ⁶ "When an accused is put on trial for a crime or misdemeanor, the correct test as to insanity is whether or not the defendant is capable of knowing right from wrong as to the particular act in question and is capable of exercising the power of choosing either to do or not to do the act and of governing his conduct in accordance with such choice"

Before Trial ⁷ "He is not considered a lunatic or insane if he is capable of understanding the nature and object of the proceedings against him, and if he rightly comprehends his own condition in reference to such proceedings and has sufficient mind to conduct his defense in a rational or reasonable manner, although upon some other subjects his mind may be deranged or unsound "

Before Judgment ⁸ "A person that becomes lunatic or insane after the commission of a crime or misdemeanor shall not be tried for the offense during the continuance of the lunacy or insanity If, after the verdict of guilty, and before judgment is pronounced, such person becomes lunatic or insane, then no judgment shall be given while such lunacy or insanity shall continue And if, after judgment and before execution of the sentence, such person becomes lunatic or insane, then in case the judgment be capital, the execution thereof shall be stayed until the recovery of said person from the insanity or lunacy In all of these cases, it shall be the duty of the court to impanel a jury to try the question whether the accused be, at the time of impaneling insane or lunatic."

Before Execution ⁹ "The defendant before execution is to be regarded as sane and not lunatic, when he has sufficient intelligence to understand the nature of the proceedings against him, what he was tried for originally, the purpose of his punishment, the impending fate which awaits him, and a sufficient mind to know any facts which might exist which would make his punishment unjust or unlawful and sufficient of intelligence to convey such information to his attorney or the court. When he has not such intelligence and mental ability he is to be regarded as insane or lunatic by the verdict of the jury, if so found, and his execution stayed or prolonged "

MALINGERING

In examining criminals for their mental condition when up for trial, the question of malingering must always be borne in mind In civil practice the patient's statements regarding delusions and hallucinations are accepted, and if in the opinion of the doctor the patient is committable, he is certified and committed to a proper hospital In the case of the criminal, especially if he is facing the electric chair or a long sentence, one must be very suspicious of any psychotic manifestations. His background, former associations and previous history must be scrutinized carefully, he must be observed, unbeknownst to him, for peculiar behavior The guards, especially on the night shift, should be interviewed regarding his cooperation and behavior on the tier

One patient examined by the Behavior Clinic, charged with murder, used insanity as his defense. When he came into the court room he presented a disheveled appearance, made many facial grimaces, at times had to be held down and was handcuffed. He attempted to disrobe before the women jurors and frequently opened the front of his trousers. Once during the trial he removed his shoes and stockings and kicked them away from where he was sitting. The trial was in the winter time and the stone floor of the court room was cold. It was observed that in his antics he tried gradually to draw his socks close to his chair so that he could rest his feet on them rather than on the cold floor. Later that night when he entered his cell, although in the court room he appeared to be totally bereft of reason, he asked the guard if he could stay up until the early morning edition of the newspaper arrived so that he could read the account of his trial. Later it was learned that the defendant's sister took lessons in stage technique so that she could make a favorable and dramatic impression before the jury as a witness for her brother.

In another case in the mental examination we elicited many delusions and hallucinations. The family came from a nearby town and gave essentially the same story as the prisoner. However, it was found that the defendant had formerly been an attendant in a state hospital, and when it was explained to him that he would be sentenced to a hospital for the criminal insane, and not the hospital where he was formerly employed, he immediately changed his story and confessed that his plan was to go to the state hospital and then run away through the help of friends.

In malingering the criminal usually changes his behavior immediately upon seeing the examining doctors. When he knows the doctor will not be around, he plays cards and carries on the regular jail routine. It is difficult for a malingerer to carry out the same behavior pattern daily for weeks, although it has been done. It is sometimes months from the time a man is arraigned before he is brought to trial so that during the interval he can be watched constantly.

Another criminal who was up for a murder made a suicidal attempt at the jail and was placed under careful, constant supervision. When seen by the doctors, he was apathetic, stared into space, and appeared to be responding to auditory hallucinations. His wife gave a detailed history of psychotic behavior for three years, following a head injury. However, upon questioning the guards, it was found that in the evening the prisoner worked crossword puzzles and played checkers with the other inmates. Three days prior to his trial he refused to eat and had to be carried to the court room. Just prior to this a letter was intercepted in which he outlined each step that

should be taken to prove his insanity, saying in part, "I am not supposed to be aware of anything, as I am supposed to be crazy. I want to impart some information to you which you in turn will give to the lawyer representing me. Don't you realize that my life hangs in the balance, that everything depends on you, as I put my trust in you? So please, for God's sake, heed my words. Don't you realize that they want to make an example of me and put me in the electric chair even though they may not be able to do it if I go to trial. It is too late to turn back now. I have gone too far and they are mad at me because if I am pronounced insane it will spoil the State's case and they will have to commit me to the Psychiatric Division until I am cured, and then I will come back and have a chance to beat the rap, because I can contend that I was not responsible for my actions. After you have copied the information burn this letter up. I want you to volunteer this information of your own accord because you naturally know all about my life." He then gave a list of friends to call upon to testify that he gave the impression of being 'unstable, irrational and unsettled', that he would always lose interest in things he was doing, he would begin a conversation and suddenly stop in the middle of it and start roaming, that he would sit and stare into space for long periods of time, and would pay no attention to those about him. He advised that all his friends be informed of this and then that they be subpoenaed to testify in court. In a twelve-page letter he outlined the steps one by one. Confronted with this evidence, his behavior changed immediately. He submitted to the mental examination and no overt signs of mental disease were elicited.

Frequently it is difficult to convince a jury that a criminal is malingering, especially if he presents many bizarre mannerisms, answers questions irrelevantly and shows peculiar behavior.

Evidence was presented to the court at the trial of one prisoner who was charged with murder that the behavior of the prisoner changed the moment a psychiatrist entered the cell tier, that if playing cards he would fall on the floor and remain there until the psychiatrist left. On one occasion he was smoking a cigarette and, upon seeing the doctor, assumed a catatonic posture, letting the cigarette burn his fingers and dropping the same when the burn became painful. At his sanity hearing he had to be carried to the witness stand, made many awkward and purposeless movements and responded irrelevantly to questions but when told to leave the stand he immediately walked to his seat. Although the psychiatrist testified that he was malingering, the jury found him insane and he was committed to a hospital for the criminal insane. After a month in the hospital for the criminal insane, he stated he would rather be tried for his offense than to spend his time with the "nuts."

On another occasion two psychiatrists testified that a criminal was insane and just before the jury was to leave the room the defendant demanded that he be heard. He testified that he stole the car by remote control, that he tried to flood the jail so that he could swim out between the bars, and then stated that he wanted to return to his mother. With this statement he broke into profuse tears and cried loudly. The jury then went to the jury room and returned with a verdict of sane. The judge sentenced him, asking him if he wished to make a statement, to which he replied "Let's match, Judge, for one to ten or one to twenty." Upon arriving in the state penitentiary he was promptly transferred to the Psychiatric Division of the prison.

MENTAL RETARDATION

Mental retardation constitutes a frequent defense by the relatives and attorneys of criminals. If the criminal has ever been in an institution for the feeble-minded, in an ungraded room in school, or did not finish the prescribed school course, this is brought to the attention of the Behavior Clinic. Before one can be tried on a criminal charge, he must have his rights restored from any previous commitment either as feeble-minded or insane. In the lower courts, it is customary to commit individuals to institutions for the feeble-minded when the I Q is 70 or below. These individuals often escape or are brought home on a parole and get into subsequent difficulties.

The Supreme Court of Illinois reviewed the case¹⁰ of a boy who was adjudged feeble-minded and committed to a state hospital for the feeble-minded at the age of 17 by the Juvenile Court of Cook County. In the order of commitment it was recited, "and the court hereby retains jurisdiction of this case for the purpose of making such further or other orders herein for the welfare of said person as may from time to time be found to be in accordance with equity and in accordance with the statute in such case made and provided." Later the boy escaped from the state hospital for the feeble-minded, and in the course of a hold-up killed a man. He signed a confession and when arraigned entered a plea of not guilty. He was examined by two psychiatrists and after their reports were given to the court the plea was changed to guilty. The defense attorney informed the court that his client understood the proceedings and the court, after warning, permitted him to plead guilty to the charge of murder. He received the sentence of death. Some time later a petition to vacate the judgment and sentence was filed. The petitioner alleged that because of his ignorance of the facts he improperly advised the boy to enter a plea of guilty and that, acting upon the petitioner's advice, the boy entered such a plea under a misapprehension. This petition was denied.

Thereafter a second petition to vacate the judgment and sentence was filed by an attorney not connected with the case previously. This petition stated that after the boy had been indicted in Criminal Court for robbery, the Juvenile Court, upon a transfer of the cause from the Criminal Court, took jurisdiction of his person.

In support of this petition an affidavit was filed by the attorney who represented the boy upon the entry of the plea of guilty. The attorney, after setting forth the commitment of the plaintiff in error to the state hospital and his escape therefrom, averred that he was not aware a plea of guilty could admit the capacity of the boy to commit the crime therein charged, that he was not familiar with the law in regard to feeble-minded persons, that he did not know the legal effect of the adjudication of the Juvenile Court, and that because of his ignorance and inexperience he advised the entry of a plea of guilty when he should have pleaded the want of jurisdiction of the Criminal Court. This petition was also denied.

The Supreme Court contended that the trial court erred in not vacating the judgment and sentence upon disclosure that the Juvenile Court had adjudged the boy a feeble-minded person and retained jurisdiction over him and that the decree was in force when his plea of guilty in the present case was entered. The criminal code required that before a plea of guilty may be entered, the court shall fully explain to the person accused the consequences of entering such a plea. A plea of guilty should be entered only when a person making it is of competent understanding and has been fully informed respecting the consequences of the plea. The plea would be of no effect if the explanation required by the foregoing section were not first made, and an explanation or warning could be of no force unless the person accused were mentally competent to understand it.

A plea of not guilty would not necessarily admit the mental competency of the person entering it, and would be consistent with a contrary contention, while a plea of guilty is inconsistent with mental incompetency, especially as it is defined in the statute under which the boy was adjudged feeble-minded. The statutory definition is: "Any person afflicted with mental defectiveness from birth or from an early age, so pronounced that he is incapable of managing himself or his affairs, or of being taught to do so, and requires supervision and care for his own welfare or for the welfare of others, or the welfare of the community." This definition, though slightly different from the statutory definition of insanity, is predicated upon mental incompetency. The general rules of law applicable to an insane person in respect to his mental competency would apply to a

feble-minded person where the defect amounts to the same lack of capacity. As a general rule, where insanity or mental incompetency is proved as existing at a particular period, it will be presumed to continue until disproved. Thus, a decree entered finding a person feble-minded shall stand and continue binding upon all persons whom it may concern until rescinded or otherwise regularly superseded or set aside. In this case of the death sentence the judgment was reversed and the cause remanded. At the subsequent trial the boy received a 100-year sentence.

Thus it will be seen that the sanity tests for feble-mindedness in the State of Illinois are the same as for insanity, and there has to be a marked degree of mental enfeeblement if a defendant cannot cooperate with his counsel or know the nature of the charge against him. On one occasion the psychiatrist testified that a man with an I Q of 44 could not cooperate with his counsel but that he knew the nature of the charge. The judge berated the psychiatrist before the assembled court, stating that in all previous testimonies he had agreed with the psychiatrist, but in this case he did not agree. The judge felt that even if the I Q were 44 the patient could cooperate with his counsel in the proper presentation of his case. The patient presented a good personal appearance and tried to answer questions. He made a plea to the court that he be released, as he wanted to marry the daughter of his godmother. When the godmother was asked about this she stated that her daughter was just a small child when the defendant was committed, that in the interim no one had communicated for him with her or any member of her family, and that she was certain her daughter was unaware of his intentions. He was charged with taking from the mails an eighteen dollar check three years before. He had been in an institution for the criminal insane in the meanwhile. He was able to tell the judge's name, the charge under which he was held, where he had worked, and the names of a few streets in Chicago. The judge offered this as evidence of cooperation. Then the attorney for the state asked the defendant if he had twenty dollars and spent eighteen dollars how much money he would have left, after a considerable period of time he replied he did not know. Evidence was presented in court that the defendant had reached the eighth grade in school but had been passed each year, finally leaving school at the age of 16. No records had been kept on his grades and no reason was given for his yearly promotions. He was unable to read or write. His mother was psychotic and she was the only living relative. With this evidence the judge sustained the testimony of the psychiatrist that the defendant was feble-minded.

In our experience many individuals who have been committed to institutions as feeble-minded are later found to have average, if not superior, I Q's.¹ It must be remembered, in evaluating I Q's, that they are never lower than estimated but may be higher, depending upon the cooperation of the person and the seriousness of the offense. One criminal with a long record who was at one time committed as feeble-minded had an I Q of 75. His psychiatrist testified that the criminal could not spell his name and that he himself considered all with an I Q of below 80 as feeble-minded and committable. At the trial it was brought out that the defendant signed his confession and jail entrance card correctly. This convinced the jury that he was of average intelligence and they returned a verdict accordingly.

We have found from experience that unless a defendant is actively hallucinating or has a history of previous hospitalization or attempts at suicide, or acts up in court, the jury will, in most instances, find him sane even if all the testimony is to the contrary. Likewise in cases of feeble-mindedness if the defendant presents a neat appearance is able to tell his name, the date, and answer correctly questions of simple calculation he will be found not feeble-minded. Occasionally the jury presents a verdict which is contrary to the evidence introduced. For instance if the only witness, a psychiatrist, testifies that the defendant is insane in some instances a verdict of "sane" is returned and the reason for the verdict, as explained by the jury, is their feeling that the defendant is trying to escape trial and punishment.

FUNCTION OF PSYCHIATRIST

To help determine the defendant's responsibility is the object of the psychiatrist in court. It is the function of the jury²¹ to decide if the defendant is sane or insane and the psychiatrist must not usurp the function of the jury. He may express his opinion and give the facts on which he bases his opinion. As the jury determines the defendant's sanity is of a civil nature not criminal, either side may call the defendant as a witness. In uncontested cases the defendant is seldom put on the witness stand and examined so that the psychiatrist is usually the only witness. The sanity jury cannot decide the guilt or innocence of the defendant nor can it make recommendations.

The psychiatrist¹² must always make a copy of the questions asked and the answers returned in the examination of a defendant. It is important to record the amount of time spent in the examination and the number of examinations made. The jury will be more favorably impressed by one who has examined a defendant on several occasions than one who has seen the defendant only once. In examinations by

order of the court all conversation can be presented before the jury. Care must be taken not to ask leading questions regarding mental illness or symptoms. Recently a young man was tried for murdering his sweetheart in a theater. A psychiatrist testified in court that the defendant was hearing the voice of his dead father talking to him at night in his cell. After this testimony was introduced in court, a guard asked the defendant the following day, "When did you ever hear voices?" To which he replied, "I didn't until they told me about it."

ALCOHOLISM

The majority of crimes of all types are committed under the influence of alcohol, or there is a history of imbibing some time prior to the crime. Records of the Behavior Clinic show 41 per cent of defendants with a history of drinking or intoxication at the time of the crime. In addition to this 11 per cent give a history of mild drinking on other occasions, 5 per cent report a history of alcoholism in either or both parents although the defendant himself does not drink, 45 per cent report abstinence from alcohol except on social occasions. It must be remembered that when in the state of voluntary intoxication one is subject to the same rules of conduct and the same principles of law as a sober man. Occasionally following alcoholism there is amnesia for the period of the offense and some time afterwards, possibly hours to days. The individual is able to recount his behavior up to the time he started to imbibe. His next recollection is usually the awakening in the police cell. On occasion an acute psychotic reaction may follow through fear, anxiety, suspense or stories told him by his fellow inmates.

EPILEPSY

Any mental deviation, no matter how slight, is considered by the defense as an excuse for commitment to a state hospital in order to dispose of the case and escape sentence. It is difficult to convince relatives and defense lawyers that psychoneurotics and psychopaths are responsible for their actions and behavior. One factor stands out, and that is that epilepsy has not been used as a defense, perhaps due to the ignorance of the defense attorney on this subject. Epilepsy is prevalent in hospital out-patient clinics, but in jail it is seldom seen and when present in a defendant it has not been used as a mitigating circumstance in the experience of the Behavior Clinic. We would expect to see furor states used as an explanation of some of the serious and offensive crimes.

THE JUDGE'S INSTRUCTIONS TO THE JURY

Prior to the deliberation of the jury on the sanity issue the judge instructs as follows 'On this hearing the jury is instructed not to consider the question as to whether the defendant in this case is guilty or not of the crime charged. The only question to be determined by you is whether or not this defendant has sufficient mentality to be tried

"After considering all the evidence in this case, if you are convinced by a preponderance of the evidence that this defendant is insane to such an extent that he does not understand the nature of the charge against him and, further, that he is unable to fully cooperate with his lawyer in a proper defense of the case, you will find by your verdict that the defendant was at the time of the impaneling of this jury, and now is, insane

'On the other hand, if you find from a preponderance of the evidence that the defendant in this case fully understands the nature of the charge and is fully able to cooperate with his counsel in a proper defense of his case, you will, by your verdict, find that the defendant at the time of the impaneling of this jury was, and now is sane

In feeble-minded cases the word "insane" is replaced by "feeble-minded"

If there is a history that the defendant has been in a state institution in any state, the following form of instruction is used. The court instructs the jury as a matter of law, that in this proceeding the jurors are not determining the guilt or innocence of the defendant. The jury is called upon only to determine from the evidence in this case whether the said _____ at the time of the impaneling of this jury has permanently recovered from his insanity. In determining that question, the jury will be governed by this test only, did the said _____ at the time of the impaneling of the jury, and now, have sufficient intelligence to fully understand the nature of the charge against him and have sufficient intelligence to understand the proceedings and sufficient mind to know any facts which might exist which could be used in his defense, and sufficient intelligence to convey such information to his attorney or to the court? If he did, then he is regarded as having permanently recovered from his insanity'

CONCLUSION

1 Any individual adjudicated insane or feeble-minded must have a restoration from his previous commitment before the state can institute criminal proceedings. The test for feeble-mindedness is the same as for insanity in Illinois.

2 By recent enactment in the State of Illinois¹³ the term "insanity" is to be applied only to criminal cases The term "mental illness" is to be used in reference to civil cases

3 We wish to suggest that society would be better protected if all persons were tried on the charges for which they are indicted, and a verdict entered Then, if the defendant is found not guilty and was insane, he could be committed to a state hospital for mental illness, or, if found guilty and the charge is a minor one, the charge could be dropped and he could be committed to a state institution where he could receive medical attention If guilty and the maximum security is desirable, he could be committed to a state hospital for the criminal insane, there to await his recovery At the present time many are found insane at the time of going to trial, and in a few years, when all witnesses and evidence have disappeared, they are restored as recovered It is necessary to dismiss the charges against them for lack of prosecution, and the individual goes free

CLINICS ON OTHER SUBJECTS

USES AND ABUSES OF QUINIDINE

J BAILEY CARTER M.D.*

QUINIDINE was first described, in 1848, by van Hevningen. It was first prepared and named by Pasteur in 1853. Quinine was used for many years for its sedative action on the heart. In 1866 Oppolzer said, "The best and most powerful factors in dealing with heart patients are three: rest, digitalis and quinine." Because of the lack of proper indications for its use and its paralyzing effect on the heart, clinicians abandoned the use of quinine. Wenckebach's attention was directed to it in 1912 by a Dutch merchant who used it to control his paroxysmal auricular fibrillation. In 1914 Wenckebach recorded the first deliberate use of it in the treatment of this condition. He exploited the very quality which had caused older clinicians to abandon the drug. In 1910 Frey studied the clinical pharmacology of the various cinchona alkaloids and found quinidine more effective than quinine, the difference being merely quantitative: the ratio 2:1.

PHARMACOLOGIC EFFECTS

Quinidine is the dextro-isomer of quinine. Both are protoplasmic poisons but quinidine is less toxic. Both depress the heart muscle. Quinidine impairs refractoriness more than contractility and is the drug of choice in cardiac arrhythmias.

PERTINENT PHYSIOLOGY OF THE HEART

The *normal heart beat* arises in the sinus node and spreads in orderly fashion and definite sequence to activate auricles and ventricles. A heart beat that originates elsewhere, in auricles or ventricles, is *ectopic* (abnormal) in origin. A series of two or more such beats constitute an *ectopic rhythm*. The abnormal rhythm may be *passive*, the result of depression of the sinus node or blocking of the impulse, or it may be *active*, the result of increased irritability of an ectopic focus. With such a focus irregularly active, *extrasystoles* of auricular A-V nodal or ventricular origin, occur. A run of two or more such

From the Department of Medicine, Cook County Hospital, Chicago.

* Assistant Professor of Medicine (Rush) University of Illinois College of Medicine.

beats constitutes *paroxysmal tachycardia* which may be auricular, A-V nodal or ventricular in type. A very rapid coordinate ectopic rhythm constitutes *auricular flutter*. Similar but incoordinate activity is characteristic of *auricular fibrillation*. Rapid incoordinate heart action may involve the ventricles as a terminal or, rarely, transitory event known as *ventricular fibrillation*. *Chaotic heart action* results if multiple ectopic foci are simultaneously active, the extent of this *combination of arrhythmias* depending on their number and location.

BEDSIDE DIAGNOSIS OF ABNORMAL RHYTHM

Exercise, amyl nitrite and atropine increase the rate of normal (sinus) rhythm. A persistent irregularity above 120 is more likely, if above 140 practically always, *auricular fibrillation*. The ventricular rate rarely exceeds 180 per minute. Exercise increases the irregularity. Innocuous arrhythmias disappear with increase in heart rate.

In *auricular flutter* the rhythm is usually regular. The relation of auricular rate (280 to 360) to ventricular rate (140 to 180) is due to 2:1 A-V block. With arrhythmia from irregular block, exercise often makes the rhythm regular. Exercise does not usually affect the rate. Vagal stimulation often causes temporary slowing, usually at half the rate, which promptly returns to the original rate when stimulation ceases. It may be ineffective, or irregular heart action may accompany the slowing.

In *paroxysmal tachycardia* the rate varies from 150 to 250 per minute. Sudden onset and cessation of a paroxysm is characteristic. In the common, benign, auricular form the rhythm is regular. In the rare but serious ventricular type the rhythm is slightly irregular, the counts varying 4 to 8 beats per minute. Exercise does not affect the rate. Vagal stimulation abruptly stops the mechanism (50 per cent) or has no effect (50 per cent).

Extrasystoles of A-V nodal or ventricular origin have a compensatory pause. The pause after auricular extrasystoles is short. Extrasystoles are more frequent in the supine than in the upright position. The arrhythmia usually disappears with increase in heart rate.

CIRCUS MOVEMENT

The conception of a "circus movement" of the excitation wave as the cause of flutter and fibrillation dates from Mayer's observations on Medusa in 1908. He induced a circus movement in the umbrella of the jellyfish by creating a local block and applying a stimulus to one side of the blocked region. The resulting contraction wave, due to the block, was forced to take an "unidirectional" course. If, after

completing the circuit the tissue from which the wave had been initiated was no longer refractory but excitable, it circled the ring again and again. If the disk was stimulated in the absence of block, the waves spread in both directions, completed half of the circumference of the disk, met and were suppressed since each was arrested by the refractory region of tissue occupied by the other. *Local blocks* rather than increased excitability is the essential factor in circus movement. A wave deflected into a circular course by local blocks can continue to circulate only if a gap of responsive tissue exists between the crest and the tail of the wave. The shorter the refractory period, the slower the transmission or the longer the path, the wider will be the gap. Closure of the gap by altering one of these conditions brings the circus movement to an end.

In the mammalian auricle, immediately after the passage of an impulse, some fibers recover more promptly and are able to respond to the next impulse while others are still refractory. This period of *partial refractoriness* creates *multiple blocks* in the auricular muscle. Since the excitation wave can spread only over responsive fibers, it is deflected from its normal course and forced to weave its way through the auricular muscle by a more devious course, its *transmission time* being considerably delayed. Conductivity is not impaired but the longer path of the impulse has the same effect. Prolonged transmission time combined with shortened refractory period permits the impulse to continue to circulate. Prolonged refractory period or shortened transmission time (due to quicker conduction or shorter path) tends to close the gap between the head and tail of the wave and to bring the "circus movement" to an end.

AURICULAR FIBRILLATION

This is the most common persistent arrhythmia. Except in hyperthyroidism it is rarely seen in the absence of definite organic heart disease. It is common in mitral stenosis, thyrotoxicosis, arteriosclerosis and hypertension. It is rare in aortic disease and in subacute bacterial endocarditis. In the *paroxysmal* type, the patient may suddenly develop tachycardia, palpitation, precordial pain, dyspnea, vertigo, nausea, pallor or even collapse. These attacks are often associated with hyperthyroidism, undue exertion, acute infection or the use of drugs, alcohol or tobacco. Recurrent or persistent attacks give rise to the *chronic* form, common in heart failure, a result of the persistently increased intra-auricular pressure. No characteristic pathologic lesion can be identified as responsible for the onset or continuance of auricular fibrillation.

The orderly sequence of auricular contraction is replaced by a self-perpetuating excitation wave within the auricular muscle. The engorged and functionless auricles show rapid, futile, fibrillary twitchings at a rate of 450 or more per minute. The ventricles, unable to respond to but relatively few of these auricular stimuli (because of functional A-V block), usually have a rate of about 120 and rarely over 140 per minute. Their contractions are totally irregular both as to force and rhythm. This rapid, irregular heart action leads to inadequate diastolic ventricular filling with resultant inability of weak contractions to open the aortic valve leaflets. A *pulse deficit* results, the difference in heart rate at apex and radial pulse varying from 10 to 100 beats per minute.

Fibrillation and flutter are similar in nature. Fibrillation is due to a circus movement within the auricular musculature which travels at a variable rate and follows an inconstant path. Flutter is due to a circus movement within the auricular muscle which follows a constant path at a constant rate.

Effects of Quinidine on the Heart—Therapeutic doses (1) *prolong the refractory period*, often by 50 to 100 per cent, (2) *slow the transmission* of the cardiac impulse, in heart muscle and from auricles to ventricles, (3) *increase the amplitude of contraction*, the prolonged refractory period with its resultant slower rate permitting increased diastolic ventricular filling, (4) *decrease myocardial excitability* by increasing the refractoriness of auricles and ventricles, (5) *slow the heart rate* by increasing the refractoriness of the sino-atrial node, which decreases the rate of impulse formation.

Effects in Fibrillation—Quinidine prolongs the refractory period of auricular muscle. Circus movement tends to die out due to inexcitable tissue in its path, i.e., "The head of the circulating wave catches up with its tail." The auricles become quiescent. Dominance of the sino-atrial node then initiates regular rhythm.

Quinidine and Digitalis—Quinidine cures auricular fibrillation by restoring regular rhythm. Digitalis does not cure it but, by its effect on auriculoventricular conduction, causes the ventricles to beat more slowly, regularly and efficiently. Both drugs prolong the refractory period and slow conduction. Their mechanisms of action differ radically. Digitalis increases the force of myocardial contraction. Quinidine depresses the restorative metabolism of the myocardium. The predominant action of quinidine is on the auricles, that of digitalis, on the ventricles. Digitalis counteracts the depressant (toxic) action of quinidine on the myocardium. Quinidine counteracts the toxic ar-

rhythmias of digitalis With toxic doses, digitalis causes systolic, quinidine diastolic arrest of the heart

Toxic Reactions from Quinidine—Undesirable effects may be the result of the drug or of the diseased heart plus the drug

Idiosyncrasy explains the sudden appearance of cinchonism which may follow a small therapeutic dose This is uncommon

Cinchonism is due to overdosage or idiosyncrasy. Tinnitus, vertigo, blurred vision, photophobia, diplopia, scotomata and dilated pupils may develop Amblyopia is usually associated with retinal ischemia Amaurosis may be followed by optic atrophy Respiratory distress, asthma or temporary cessation of breathing may occur, as may nausea, vomiting, abdominal pain and diarrhea. Headache, fever, apprehension, excitement, confusion, syncope, delirium and coma have been noted Renal damage, with anuria and anemia, has been ascribed to quinidine The skin is often flushed and sweating Rashes, angio-neurotic edema or inflammatory swelling may appear

Tachycardia due to flutter during the transition of fibrillation to regular rhythm may be dangerous

Ventricular fibrillation is responsible for many fatalities previously attributed to embolism Antecedent tachycardia can often be prevented by previous digitalization

Ventricular standstill, temporary or fatal, may occur during the period of auricular quiescence, due to sino-atrial and/or auriculoventricular block

Embolism has been overemphasized It is no more frequent with proper quinidine therapy than with digitalis or no medication

Contraindications to Quinidine Therapy.—

- 1 Idiosyncrasy
- 2 Severe cinchonism
- 3 Acute infection
- 4 Bacterial endocarditis
- 5 Extensive myocardial disease as evidenced by
 - (a) Cardiac hypertrophy or enlargement
 - (b) Valvular disease and/or
 - (c) Fibrillation of long standing
 - (d) Coronary occlusion
 - (e) Heart failure
- 6 Aged patient or one in whom a return to regular rhythm is unlikely or is not particularly desirable
- 7 Hyperthyroidism prior to thyroidectomy Normal rhythm often reappears after operation. When fibrillation is stopped by quinidine before operation it may reappear afterwards

- 8 Angina pectoris, relieved by the onset of fibrillation
- 9 Embolism usually precludes use of the drug with safety, although recurrent episodes in an otherwise benign fibrillation may justify its use
- 10 Complete heart block Nothing is gained by restoring regular rhythm The ventricular rate is increased, extrasystoles appear, tend to form groups, and may initiate an attack of ventricular tachycardia or fibrillation Partial block is not a contraindication but indicates careful graphic control of therapy Progress of a conduction defect or the onset of a new, abnormal rhythm prohibits further use of the drug

Contraindications cannot be absolute Each case is a law unto itself

Indications —

- 1 Auricular fibrillation persisting more than three days after thyroidectomy * Regular rhythm is restored in 90 to 95 per cent of these cases Delay increases the percentage of failures
- 2 Young patient with little heart damage but with a distressing arrhythmia of recent origin
- 3 Arrhythmia after, not during, an acute infection or following operation
- 4 Patient whose chief complaint is intractable palpitation in spite of all other treatment
- 5 In otherwise hopeless cases when all other therapy has failed
- 6 In mitral disease with persistent extrasystoles and in fleeting, distressing, undiagnosed arrhythmias quinidine may delay the onset of auricular fibrillation

Absorption and Excretion — Quinidine is readily absorbed and quickly excreted in the urine Cumulative effects need not be feared Relatively large dosage at short intervals is essential to successful therapy

Preparations — Quinidine sulfate, the official U S P preparation commonly employed, occurs as fine, needle-like, white, odorless, bitter crystals which darken on exposure to light It is soluble in water (1 90) and in alcohol (1 10)

Clinical Uses — Quinidine decreases morbidity but does not reduce mortality The presence of auricular fibrillation, per se, is not an indication for its use An adequately digitalized, chronically fibrillating heart is no less efficient than it is after restoration of regular rhythm by quinidine If such a patient is heart conscious or uncom-

* The incidence of auricular fibrillation in thyrotoxicosis is from 5 to 10 per cent. After operation 45 per cent of cases return to regular rhythm and 15 per cent more revert eventually In 40 per cent of cases fibrillation continues after operation, unless quinidine is used

fortable or if his activity is restricted because of palpitation, quinidine may be helpful. Some patients are more uncomfortable after restoration of regular rhythm than with fibrillation. Digitalis is indicated in heart failure and subsequent use of quinidine is seldom justifiable or successful. The advisability of combined therapy is questionable. Digitalis should be used in most cases of fibrillation. Quinidine is indicated in relatively few instances. Digitalis to slow tachycardia before using quinidine is advisable. Persistent postoperative fibrillation in thyrotoxicosis and arrhythmias following infection or operation in young adults with relatively sound hearts are well treated by quinidine. Results in arteriosclerosis and hypertension are poor. Before using quinidine the clinician must weigh possible benefits to be derived against possible dangers incident to the use of the drug.

A careful selection of patients is essential to successful quinidine therapy. Insistent demand that each candidate have a relatively intact myocardium increases the likelihood of the arrhythmia being adequately controlled. In from 75 to 90 per cent of properly selected and treated cases a regular rhythm is restored and in over 90 per cent of these recurrence of fibrillation will not take place if an individually determined maintenance dose is faithfully continued. Lack of success with quinidine reflects failure to evaluate properly the importance of a relatively sound heart.

Therapeutic Management—The patient should be at complete bed rest, in a hospital, under mild sedation and close medical observation. A preliminary assay of the heart muscle is desirable. A ventricular rate above 100 should be lowered by digitalis. Digitalis prevents the occurrence of ventricular tachycardia after quinidine. Heart failure calls for digitalis.

METHODS OF ADMINISTRATION—Scored tablets (0.2 gm.) by mouth are most suitable. Vomiting, collapse or coma may preclude oral use of the drug. A soluble preparation for intramuscular use is obtained by the following formula:

	Gm. or cc.
Quinidine hydrochloride	15
Antipyrine	15
Urea	20
Distilled water	to make 100

The mixture is a clear, colorless solution with 0.15 gm. of quinidine hydrochloride in each cubic centimeter. Preparation of this solution is not difficult. The ingredients are readily available. Sterilization is by Berkefeld filter. Storage in stoppered bottles makes it available for emergency use. This, like all quinine solutions, turns brown, but

there is no change of potency or increase in toxicity. An initial dose of 0.45 gm. is repeated every two hours according to specifications given below. Pain, local reaction and toxic manifestations are slight. Intravenous quinidine is dangerous and should be employed rarely. A solution is made by vigorously shaking 4 gm. of quinidine sulfate in 500 cc. of 5 per cent glucose. This is filtered, warmed slightly and given at the rate of 100 cc. per hour. Frequent determination of the apical pulse and blood pressure during administration is essential. A sudden drop in blood pressure is best treated by caffeine sodiobenzoate, 0.5 gm. intravenously.

TECHNIC OF DOSAGE—Of the methods of administration the one described is probably as safe and effective as any. A test dose of 0.2 gm. is given the day before treatment is started and the patient is carefully observed by symptoms or signs of idiosyncrasy or cinchonism. The following morning 0.4 gm. is given every two hours until (1) regular rhythm at a slow rate is restored,* or (2) 4 gm. of the drug has been given,† or (3) cinchonism, definite and severe, develops, or (4) tachycardia, above 140, occurs, or (5) frequent and persistent extrasystoles presage ventricular fibrillation, or (6) showers of petechiae suggest the imminence of embolism.

Upon restoration of sinus rhythm the next dose is halved (0.2 gm.). If the rate remains regular the interval is doubled, i.e., the next half-dose (0.2 gm.) is given four hours later. This dosage is continued for the next twenty-four hours, 0.2 gm. four times a day, and finally 0.2 gm. three times a day before meals, being tried as a temporary ration. Reduction in dosage depends on the condition responsible for the arrhythmia, the total amount required to reestablish normal rhythm, the age and condition of the patient, the state of the myocardium and the urgency of the situation. One may well vary the routine outlined above. When the patient becomes ambulatory the

* It is essential that a physician, resident or intern, thoroughly acquainted with quinidine therapy, personally determine the apical heart rate before giving the next dose of the drug, an electrocardiogram every two to four hours during therapy, is helpful and, in certain cases, essential.

† Dosage depends on the age, weight and vitality of the patient, on the condition of the myocardium and on the urgency of the situation. A dose of 4 gm. is safe for the average individual as is 5 gm. for a sturdy patient with a relatively intact myocardium, whereas 3 gm. for a frail, ill or aged patient may constitute a large dose. We have rarely used 6 gm., and 8 gm. in only one instance. Here it failed to control a rapid ventricular tachycardia in a badly damaged heart in failure following coronary occlusion after digitalis, two previous courses of 5 and 6 gm. of quinidine, papaverine, magnesium sulfate and potassium chloride had failed to slow the rate. Digitalis, being resumed, slowed the rate, lessened the decompensation and temporarily increased the patient's comfort.

maintenance dose must be determined again. Provided the underlying disease is not unduly progressive, increased tolerance causes little trouble. A daily ration determined in August 1931 remains adequate in December 1944 without evidence of harmful effects.

A "course" may be repeated two or more times at intervals of a day to a month, depending on the rate of recovery of the heart and the urgency of the situation. More than three attempts are rarely justified and are usually futile.

'Courses' employing smaller dosage and/or longer intervals have not been successful owing to the prompt absorption and rapid excretion of the drug.

AURICULAR FLUTTER

Less effective here than in fibrillation, quinidine therapy, as previously outlined, has been more effective than digitalis. Some practi-

Fig 38—After collapse on February 25, 1939. Auricular flutter with irregular rate and rhythm due to variable A-V block. Note the appearance of Lead I Chest lead IVR.

tioners reserve quinidine for those who fail to respond to digitalis, but earlier experience has influenced us to use quinidine first and digitalis later. Flutter without failure is best treated with quinidine. With failure digitalis should be used. Quinidine is the initial choice in the treatment of uncomplicated flutter.

Case History—A man, aged 48 years, who was first seen on March 24, 1939, with pain in his left chest, shoulder and arm, dyspnea

Fig 39—On examination March 24 Rate auricular 270, ventricular 90 Rhythm regular Chest leads CRIV and V, as in subsequent records

and weakness following "flu" four months previously, had collapsed on February 25, and again on March 17, 1939. Two courses of quinidine, 0.2 gm thrice daily and 0.4 gm four times daily for a week, each had failed to bring relief, and the patient was told that nothing further could be done.

Examination revealed a regular rhythm at a rate of 90 per minute uninfluenced by exercise or vagal stimulation. The blood pressure was 136/84-80. The apex beat was not seen or felt. The heart borders

were within normal limits except for dullness of the lower sternum and prominence of the left auricular area. There was no murmur or thrill and no rales in the lung bases were heard on auscultation. The liver and spleen were not felt and no ascites or ankle edema was present. The blood and urine were negative. X-ray findings were confirmatory. The electrocardiogram revealed an auricular flutter with an auricular rate of 270 and a ventricular rate of 90 per minute, a 3:1 A-V block being present.

Fig. 40—On March 28, during quinidine therapy

After three days of bromide therapy and rest at home with a test dose of 0.2 gm of quinidine on March 25, the patient entered the hospital on March 27 for treatment. Quinidine sulfate, 0.4 gm was given by mouth at two-hour intervals on March 28 from 8 A.M. to 10 P.M., a total of 3.2 gm. in fourteen hours. The heart rate thereafter was 80 and regular. Quinidine 0.2 gm was given at midnight and this dose was continued every four hours until the patient was discharged on March 30. He continued the drug, 0.2 gm thrice daily. After April 2 he took the same dose twice daily. After September

25 he took one dose of 0.2 gm each morning. Since October 11, 1939, he has reduced this morning dose to 0.1 gm. After hospitalization activity was gradually resumed. He worked part time after three months, full time after six months, as a laborer, and has remained well.

Fig 41—On March 29, after successful therapy

PAROXYSMAL TACHYCARDIA

With *auricular* or A-V nodal tachycardia, a younger patient and a relatively sound myocardium, contraindications are fewer. The dosage may be smaller and at longer intervals. Oral administration of 0.2 or 0.4 gm three times a day before meals or four times daily usually relieves these paroxysms. Parenteral therapy is rarely necessary.

Although the condition may occur without preceding or subsequent damage, *ventricular* tachycardia is usually associated with extensive heart disease. In this grave arrhythmia, although the drug is dangerous and may cause fibrillation and death, its action at times is dramatic and life saving. Results are often unsatisfactory. A high mortality is to be expected. If the oral route is not available, intramuscular in-

jection should be used, intravenous medication being reserved for obstinate or moribund cases. Quinidine is toxic and, as mentioned previously, its intravenous use is dangerous and rarely justified.

Fig. 42—On September 25 six months after therapy

EXTRASYSTOLES

This arrhythmia if asymptomatic is not an indication for medication. Factors responsible for the extrasystoles should be removed. Relief and/or prevention of recurrences then will be successful in most instances. Quinidine affords relief by decreasing myocardial irritability when this is the basis for extrasystoles. For the ambulatory patient, doses of 0.2 or 0.4 gm. three times a day before meals or four times daily are usually sufficient. The drug may be helpful in overcoming distressing palpitation and heart consciousness and affords reassurance that something can be done should the need arise. Quinidine may control the extrasystoles of digitalis coupling. Digitalis n

quinidine, should be used to control extrasystoles due to heart failure. Rest, bromides, belladonna, strychnine and quinidine, papaverine or digitalis may be preferred or required in certain instances.

CORONARY OCCLUSION

Quinidine has been advised to reduce myocardial irritability and to lessen the incidence of ventricular tachycardia and fibrillation after infarction. These arrhythmias, following coronary occlusion, are relatively rare. The routine use of a drug, wholly depressant in its action on the myocardium, is not justifiable. Ventricular tachycardia following infarction justifies its use.

CAUSES OF FAILURE

Usually the lesser action of quinidine is depression of conductivity and the greater effect is prolongation of the refractory period. If the predominant action of the drug is on the refractory period it tends to stop fibrillation. If its effect on conduction predominates, this tends to perpetuate and fix the mechanism. Idiosyncrasy may prevent treatment. Unwarranted fears concerning its dangers may result in inadequate dosage. Toxic symptoms may prevent adequate dosage. Failure is most often the result of improper selection of cases.

SUMMARY

Quinidine is an ideal drug. It is inexpensive, easily obtainable, promptly absorbed, powerful in action but rapidly excreted and can be given orally or parenterally. It has a high degree of effectiveness combined with relatively low toxicity. It is indicated for the control of certain arrhythmias in relatively sound hearts. It should be given in larger doses at shorter intervals than heretofore. Success with the drug reflects judicious selection of cases. It is a valuable drug if properly used.

PERNICIOUS ANEMIA

GEORGE E. FARRAR, JR., M.D. * AND HAROLD L. HYMAN, M.D. †

CLINICAL recognition of primary (Addisonian) pernicious anemia is facilitated by the neurologic and gastrointestinal symptoms which are frequently present. Chronic and mild anemias of the iron deficiency type (hypochromic and microcytic) are often not recognized until an examination of the blood demonstrates a low hemoglobin level. The symptoms of chronic anemia *per se*, occur in other common clinical conditions. Such symptoms are weakness, fatigue, shortness of breath and palpitation on slight exertion, dizziness with exertion or change of posture and mild swelling of the ankles by the end of the day. Pallor is often insufficient to demand attention and may be masked by cosmetics. In the macrocytic anemias the frequently associated stomatitis interferes with the recognition of pallor of the mucous membranes and the slight icterus of the skin and sclerae is confusing especially in artificial light. Conversely pale patients are often found to have essentially normal blood counts, because pallor has other causes than anemia such as edema and myxedema and even more commonly the vascular pallor of the skin which is associated with a great variety of chronic illnesses.

The diagnosis of primary pernicious anemia should be restricted to cases presenting achlorhydria gastrica after the hypodermic injection of histamine, and showing a macrocytic anemia. The patient with pernicious anemia also shows atrophy of the gastric mucosa and often of the tongue, increased numbers of nucleated erythrocytes in the sternal marrow, including more than 2 per cent megaloblasts (nucleus has reticular chromatin and often nucleoli, cytoplasm is deeply basophilic and contains some hemoglobin), a continued need of and response to liver extract and often a history of pernicious anemia in the family. Symptoms may be precipitated by a deficient intake of food (particularly animal protein) due to loss of teeth, change in economic status or food fadism. Patients with only traces of intrinsic

† Associate Professor of Medicine, Temple University Medical School and Hospital, Associate Physician, Protestant Episcopal Hospital of Philadelphia

‡ Resident Instructor in Medicine, Temple University Medical School and Hospital, Philadelphia

sic factor may remain well as long as large amounts of extrinsic factor are ingested. In the hematology clinic many patients presenting the diagnostic criteria of primary pernicious anemia also show definite evidences of malnutrition, disease of the liver, hypometabolism, etc. The term secondary pernicious anemia often seems appropriate.

CLINICAL TYPES OF PERNICIOUS ANEMIA

Minot presented a clarifying analysis of the symptomatology of one hundred patients with pernicious anemia in his private and clinic practice. Patients were divided, according to their symptoms, into four groups as follows:

1 **Gastrointestinal** Thirty-one cases—sore mouth, anorexia, epigastric fullness after meals, constipation, nausea, diarrhea, dyspepsia suggesting peptic ulcer or biliary tract disease.

2 **Neurological** Twenty-six cases—numbness and tingling of the feet and, less often, of the hands, difficulty in walking, stumbling in the dark, urinary incontinence, headache, psychic disturbances.

3 **Generalized or anemic** Thirty-three cases—fatigue, weakness, dyspnea, palpitation, vertigo, usually marked pallor.

4 **Cardiac** Ten cases—angina pectoris, dyspnea, palpitation, edema of the ankles, weakness, usually marked pallor.

Minot noted that symptoms had been present for an average of 2.19 and 1.28 years in groups 1 and 2 respectively before the presence of pernicious anemia was suspected. In contrast, pernicious anemia was diagnosed in less than one year in the anemic and cardiac clinical types.

In general medical work Minot's emphasis on the paresthesias, sore tongue and indigestion is very helpful in the recognition of pernicious anemia.

GASTROINTESTINAL

CASE I—Miss J. F., aged 71 years, was admitted to the ward with complaints of one year's duration as follows: progressive weakness, epigastric fullness, belching and sometimes nausea and vomiting after meals, anorexia, dyspnea and palpitation after walking one block, swelling of the ankles at the end of the day, dizziness, numbness and tingling of the feet and hands, loss of 40 pounds of weight. Her friends reported that her skin became yellow about one year ago.

Physical examination showed an elderly white woman, whose skin was dry, glossy, thin and lemon-yellow in color. The right eye showed the results of a successful cataract extraction, phthisis bulbi had followed extraction in the left eye. The entire tongue was smooth and shiny. She was wearing false teeth, the gums were in good condition. The heart was enlarged to the left, a loud, blowing systolic murmur

was heard over the entire precordium. The blood pressure was 120/60. The peripheral arteries felt moderately beaded. The hands were deformed by advanced osteoarthritic changes and there was bilateral hallux valgus with bunions. The patellar reflexes were hyperactive. Both position and vibration sensations were almost absent in the legs. The Romberg test was positive. Pelvic examination revealed only senile changes.

Urinalysis and the serologic test for syphilis gave negative results. Examination of the blood showed hemoglobin 5 gm per 100 cc (33 per cent), red cells 146 million per cu mm, leukocytes 8100, differential leukocyte count, neutrophils 41 per cent (nonfilamented 8 per cent, filamented 33 per cent), lymphocytes 53 per cent, monocytes 5 per cent, eosinophils 1 per cent. The mean corpuscular volume was 123 cubic microns, the color index was 1.18, a modified Price-Jones curve showed 25 per cent of erythrocytes to be less than 7.5 microns in diameter, 17 per cent equal to 7.5, and 58 per cent larger than 7.5 (normally about one third of the cells are in each category). Erythrocytes varied from 3 to 13.5 microns in diameter. X-ray examination showed no abnormality of the gastrointestinal tract with a barium meal, but showed enlargement of the left ventricle and calcification of the aorta in the chest. Gastric analysis after histamine injection showed no free acid.

Ventriculin NNR was administered orally in doses of 10 gm four times a day, in an attempt to assay the potency of a new supply of this defatted hog stomach preparation. The reticulocyte count reached 18 per cent of the red cells on the fifth day of treatment and remained at 18 or 19 per cent for the next four days before decreasing, instead of rising to the peak of about 28 per cent which would be expected from the initial erythrocyte count. The red cell count, however, increased to 2.9 million at the end of two weeks of treatment (see Table 3). It did not rise further after three and four weeks. At this point fever and leukocytosis (white blood cells 16,200, neutrophils 67 per cent) developed. An ischio-rectal abscess was found, incised and drained. The patient was discharged after seven weeks in the hospital with a blood hemoglobin level of 11 gm and an erythrocyte count of 4.5 million.

In the outpatient clinic she received weekly injections of 6 units of liver extract USP for seven months. The red cell count varied between 4 and 5 million and the hemoglobin between 13 and 14 gm and she felt well. During the next three months treatment consisted of 10 gm of ventriculin daily by mouth, the erythrocyte count fell to 3.8 million but it rose in four weeks with parenteral liver therapy to 4.5 million. During this month, gastroscopic examination, performed by Dr. C. L. Jackson, showed atrophic gastritis, the tongue was coated on its posterior third and the anterior third although clean was not red, and both the filiform and the fungiform papillae

appeared normal Parenteral liver extract in doses of 10 units was given three times a month for six months After one and one-half years of treatment the patient was in good general condition for her age She had gained 20 pounds in weight The blood hemoglobin level was 13 gm, the red cells numbered 5 million and the mean corpuscular volume was 84

She remained in good health for two and one-half more years (five years after onset of symptoms) when severe ichthyosis and partial intestinal obstruction, due to inoperable adenocarcinoma of the ovary, developed Pelvic examination had been negative four years before Sternal marrow was aspirated and found to be hyperplastic but not megaloblastic The patient lived another year and a half with one course of x-ray therapy and injections of 30 mg of testosterone propionate three times a week for six months After testosterone was discontinued because there was no objective change in the size of the pelvic tumor, she deteriorated rapidly and died in eight weeks with complete intestinal obstruction at the age of 77 years Autopsy confirmed the diagnosis and disclosed metastases in the liver During the last year of life abdominal cramps after meals caused anorexia and the red cell count did not rise above 3.5 to 4 million in spite of continued parenteral liver therapy (10 units weekly)

Comment—It is unusual for patients with pernicious anemia to lose as much weight as 40 pounds, but in spite of this woman's age she regained 20 pounds A poor reticulocyte response and a slow rise in red cell count occurs with oral treatment in a few patients Both infection and senility, as well as poor gastrointestinal absorption, are often associated with an unsatisfactory response to oral therapy The prolonged, submaximal increase in the reticulocyte count indicates an inadequate dose of anti-anemia substance The subsequent failure of oral therapy to maintain this patient's blood count at a normal level is best explained by inadequate intestinal absorption, since parenteral liver therapy was effective even after carcinoma of the ovary appeared

NEUROLOGICAL

CASE II—Mr W S first came to the Neurology Outpatient Clinic in May, 1939 His complaints had commenced one year before with painful corns on both feet, not relieved by wearing arch supports, and nausea after meals His symptoms included progressive weakness, loss of voluntary control and partial anesthesia of both legs, particularly of the feet, and a loss of equilibrium while standing or walking He found it very difficult to walk without watching his feet, and with his eyes closed or when in the dark he fell During the winter his feet felt very cold to his hands but he was not conscious of their being so cold Increasing sexual impotency had been present for one

and one-half years and lately he had frequently experienced urinary incontinence. Numbness and tingling in his fingers and toes were unpleasant. Poor memory was troublesome at his work as a clerk in a freight yard and he had become irritable, sensitive and antagonistic. Three years previously he fractured his left ankle and was unable to work for eight weeks. Four years previously he lost money gambling and, because of this debt, he was unable to provide for his wife and three children. His wife left him temporarily two years previously and during this period he lost 50 pounds in weight. He had since regained 30 pounds.

TABLE 1—RESULTS OF NEUROLOGICAL EXAMINATIONS IN CASE II

Date	1939		1940	1941	1942	1943

Examination performed by Dr. Sherman F. Gilpin.

Key: + indicates present or, in the case of reflexes, increased; 0 indicates no abnormality; -- indicates decreased; --- indicates absent.

Physical examination showed a pale white man appearing his stated age of forty-three years. There was no evidence of acute distress. The tongue was clean, smooth, shiny and pale. Nothing abnormal was found in the chest and abdomen; the blood pressure was 110/80. The neurologic examination is recorded in Table 1. The feet were markedly pronated and the anterior arch was flat. The finger nails were brittle and spoon-shaped (koilonychia).

Urinalysis and the blood Wassermann test gave negative results. Only very small specimens could be obtained on gastric analysis and there was no free acid after histamine stimulation. Anemia was very mild, considering the patient's pallor, and normochromic. Blood count results were hemoglobin 12 gm (71 per cent), red cells 3.6 million,

color index 1, white cells 6450, differential leukocyte count, neutrophils 61 per cent (nonfilamented 7 per cent, filamented 54 per cent), lymphocytes 37 per cent, monocytes 1 per cent, eosinophils 1 per cent. Unexpectedly, the aspirated sternal marrow was hyperplastic and megaloblastic (see Table 2)

TABLE 2 —CYTOLOGY OF ASPIRATED STERNAL BONE MARROW IN CASE II

Cell	Per Cent	Normal Range, Per Cent (Osgood)
Granulocytes		
Segmented, Neutrophils	13.5	7-25
Eosinophils	2.5	0-1
Basophils	0	0-0.2
Nonsegmented, Neutrophils	17.0	15-35
Eosinophils	3.5	0-3.6
Basophils	0	0-1
Metamyelocytes, Neutrophils	4.0	1-10
Eosinophils	0.5	0-2
Myelocytes, Neutrophils	1.0	0-10
Promyelocytes	2.5	0-10
Myeloblasts	2.5	0-2
Lymphocytes	5.0	4-16
Monocytes	5.0	0-5
Normoblasts	13.0	2-10
Pronormoblasts	7.5	2-15
Erythroblasts	19.0	0-5
Megaloblasts	3.5	0-0.2
Granulocytes—Nucleated erythrocyte	1.2/1	2/1-9/1

(This marrow film shows a marked increase in nucleated red cells (megaloblasts and erythroblasts) and a slight increase in eosinophilic leukocytes. Two areas of 200 cells each were counted.)

Parenteral liver extract therapy was commenced on June 14 with 60 anti-anemia units USP, this dose was repeated the next day and 20 units were given on June 16 and 17. His legs felt stronger on June 15. Thirty units were then injected intramuscularly every week for two months. On July 12 there was no improvement in symptoms and the blood examination showed a decrease in hemoglobin to 10.5 gm with practically no change in the red count which was 3.55 million. Ferrous sulfate, exsiccated USP X, in doses of 0.2 gm was prescribed three times daily before meals. On August 9 there was still no clinical improvement and, although the blood count was better (hemoglobin 11.5 gm, red cells 4.8 million), anisocytosis was still marked on the blood film. During the next two months, 20 units of liver extract were injected weekly. On October 4 the patient felt generally well, his memory and irritability had improved and he found it less difficult to walk (see Table 1). The laboratory report was almost normal (hemoglobin 12.5 gm, red cells 4.24 million) and an abnormal variation in the size of the erythrocytes was no longer no-

useable During the next two months the dose of liver was increased to 30 units weekly. On November 19 the blood hemoglobin was 14 gm and the red count 4.9 million. By mid-December, about six months after treatment was started, the patient felt that his symptoms were about 90 per cent relieved. He still experienced difficulty in walking or even standing in the dark and he slapped the forepart of his foot on the floor as he walked.

From December, 1939 to March, 1940 intramuscular injections of 15 units of liver extract were given every two weeks. In February gastric analysis was repeated with histamine stimulation, achylia gastrica persisted unchanged. Since the neurologic findings seemed slightly but definitely worse than in October, 1939 (see Table 1), the dose of liver extract was again increased to an average of 2 units per day—i.e., 30 units every two weeks—which has been maintained every since. Dilute hydrochloric acid USP in a dose of 2 cc. ($\frac{1}{2}$ teaspoonful) in a full glass of water with breakfast and dinner was prescribed in addition to the ferrous sulfate which the patient had been taking. In May, 1940, the application of metatarsal pads to his shoes alleviated most of the remaining symptoms with his feet. Eleven blood counts between November, 1939 and February, 1944 have shown hemoglobin values between 12.5 and 14.5 gm and red cell counts between 4.41 and 5.1 million. In February, 1941, liver injections were changed from 30 units every two weeks to 60 units of reticulogen (Lilly, 3 cc.) every four weeks. Reticulogen also contains 10 mg of thiamine per cubic centimeter. Symptomatically and to casual observation this man remains cured except for pronated feet and metatarsalgia. Some abnormalities persist in the neurologic examination.

Comment—This man illustrates a moderately severe instance of posterolateral column degeneration associated with achylia gastrica but with only a mild, normochromic anemia. Except for the finding of the megaloblastic sternal bone marrow, this case would be classified as an idiopathic combined degeneration of the spinal cord rather than a pernicious anemia. The idiopathic cases do not respond as well to liver therapy and do not show a megaloblastic marrow. It is interesting that this patient experienced severe neurologic disturbances for almost a year without developing sufficient anemia to be recognizable as pernicious anemia. The slowness of the response to liver therapy (three months before any response and six months before marked improvement), the persistence of abnormal neurologic findings, the initial necessity and continuing need for an average of 2 or even more units of liver extract daily parenterally and the diagnostic value of aspirated sternal marrow are illustrated in this patient.

GENERALIZED OR ANEMIC

CASE III—Miss E. M., aged 70 years, was admitted to the ward in March, 1935, because she was struck by an automobile in front of the hospital. Aside from contusions and fractures of the left fifth to ninth ribs received in the accident her history was as follows. Two years previously her tongue was sore for many weeks. The following spring she experienced dyspnea and weakness on slight exertion as well as a sore tongue. About four weeks before admission these symptoms recurred together with orthopnea, pallor and swelling of the ankles. Bed rest for one week relieved the dyspnea and ankle edema. The other symptoms improved on medication with oral liver extract, iron and hydrochloric acid. Until recent years she had been employed as a practical nurse. She had been living alone in a rooming house and her only support was her old age pension.

Physical examination showed a well-nourished and unusually well-preserved white woman with an icteric pallor. Her tongue had a white coating. A mucopurulent postnasal discharge was visible. The heart and lungs were clear except for the fractured ribs and occasional extrasystoles, the blood pressure was 112/68. Vibratory sensation was impaired in the legs. Fresh retinal hemorrhages and old scars were seen in both eyes.

Urinalysis and the Wassermann and Kahn tests gave negative results. In addition to the fractured ribs, roentgenographic examination revealed spondylolisthesis, osteoarthritis of the spine and osteophytes arising from the inner table of the skull. An electrocardiogram showed only left axis deviation. No free acid was obtained on gastric analysis with histamine. The blood count was hemoglobin 5.8 gm (40 per cent), red cells 2 million, mean corpuscular volume 114. After treatment with intramuscular liver extract, 2 units daily for one week, the reticulocytes increased to 23 per cent on the seventh day, exceeding the average peak of 19 per cent to be expected (see Table 3) from the initial red cell count. With 2 units twice a week, together with 2 cc of dilute hydrochloric acid USP with meals and 2 gm of iron and ammonium citrate USP three times daily by mouth, the hemoglobin had increased to 10.5 gm and the red cell count to 4 million when the patient was discharged from the hospital at the end of seven weeks (see Fig. 1).

She did not return to the clinic for three months and only irregularly thereafter for one and one-quarter years. During these fifteen months she ate liver two or three times a week and received 20 injections of 2 units of liver extract, five erythrocyte counts varied between 4.5 million at three months and 2.6 million after eighteen months. After 20 weekly injections of 2 units, the red cells had increased to 3.8 million and the mean corpuscular volume was 102. When six weekly doses of 6 units each were given the blood picture approached normal, hemoglobin 12 gm, red cells 4.75 million, mean

corpuscular volume 80 During the next fifteen weeks (May-June, July 1937) she came only seven times and received a total of 42 units, the erythrocyte count decreased to 3.9 million and the mean corpuscular volume increased to 90 on this inadequate dosage (average of 0.4 units daily) Weekly doses of 6 to 10 units thereafter maintained normal blood counts Gastroscoy, performed by Dr. Lester Morrison in August 1938 demonstrated atrophic gastritis and the basal metabolism was minus 28 per cent but there was no clinical evidence of myxedema

An episode of acute hemorrhoidal bleeding, corrected by sclerosing injections, occurred in January 1939 and was followed in March by a severe attack of herpes ophthalmicus and months of postherpetic neuralgia In spite of an increase in the dose of liver to 20 units every two weeks the erythrocyte count remained between 3.6 and 4 million Liver was discontinued entirely during August, September and October 1939 and ferrous sulfate 0.2 gm. was used four times daily by mouth, the red cells decreased to 2.9 million with a hemoglobin of 9.5 gm. After 10 units of liver extract were injected twice weekly for six weeks the red count increased to 4.5 million While on 10 units weekly and later 30 units every two weeks the red cells varied between 3.5 and 4 million between January and September, 1940 Re-examination by the Cardiac Clinic again revealed no significant abnormalities and the Neurology Clinic reported a normal examination except for the absence of vibratory sensation in the legs, which is common in persons of this age without pernicious anemia The basal metabolic rate was minus 10 per cent and the blood cholesterol 323 mg. per 100 cc. with 150 mg. (46 per cent) in the ester form The patient discontinued taking desiccated thyroid after two days because of nervousness, tachycardia and insomnia During August she experienced severe reactions at the site of liver injections Liver therapy was changed to a horse-liver extract in doses of 7 units weekly intramuscularly and at the end of six weeks the erythrocyte count reached 4.5 million for the first time in ten months Because of a dry skin and pruritus, which she attributed to liver extract, she discontinued treatment and the red count dropped to 3.5 million in six weeks

Parenteral liver therapy was commenced again in June, 1941 In spite of the regular administration of 30 units every two weeks the red count has varied between 3.5 and 4 million (rarely 4.5) with a color index of about 1 The patient is now seventy-nine years old She is in good health with this dose of liver, except for pain associated with osteoarthritis and senile osteoporosis with compression of the bodies of the midthoracic vertebrae

Comment—This patient has required continuous use of liver extract. Weakness and a decrease in the erythrocyte count have recurred in about six weeks whenever liver has been discontinued and whenever

the average dose has been less than 1 unit per day (see Fig 43) In general she has been well and active during the eleven years since the onset of her symptoms at the age of sixty-eight years The absence of neurologic or gastrointestinal symptoms of pernicious anemia throughout has been striking In recent years even large doses of liver (30 units every two weeks for nine months) have not maintained an erythrocyte level of 4.5 million per cu mm Perhaps this is explained

Fig 43—The red blood cell count in millions per cubic millimeter, the hemoglobin in grams per 100 cc of blood and the anti-anemia therapy in Case III during eight of the nine years of observation is presented Intramuscular injections of liver extract are charted in USP units for the preceding four weeks In the date column, the letters indicate March, June and September Important intercurrent events are noted

by the lower normal erythrocyte counts observed in aged persons, but in addition this woman is unable to purchase an adequate diet Her weight has remained between 150 and 160 pounds for nine years, but her diet contains very little meat, egg or dairy products Hydrochloric acid was discontinued after many months because of the abdominal distress and regurgitation after meals which it seemed to cause

CARDIAC

CASE IV—Mr A Del T was a 56 year old, married native of Puerto Rico For five weeks before admission he had experienced a severe, squeezing substernal pain after exertion This became more frequent and was induced by the slightest activity Numbness of the legs and

fingers was noticed About three weeks previously, swelling of the ankles and legs, weakness, dyspnea and palpitation on any exertion developed and became progressively worse until he was bedridden All of his teeth were extracted one week earlier on the advice of a physician Memory of his early life was almost absent For several years he had experienced stiffness of his fingers during the winter Six years ago he had visited the outpatient clinics of this hospital because of a severe generalized dermatitis, no cause was established at that time and a complete blood count showed no abnormality except eosinophilia (white blood cells 5800, eosinophils 19 per cent) He had been employed cleaning railroad passenger cars for many years He had two adult children

Physical examination revealed a quiet, middle-aged man lying flat in bed Weight loss was evident The skin was light tan in color His black hair was gray at the temples The sclerae and mucous membranes of the mouth were icteric The gums of both the upper and lower jaws had not healed since the recent extractions The tongue was coated (no redness nor smoothness) The lungs were clear The heart was not enlarged A soft systolic murmur was heard over the precordium and in the left axilla The rhythm was regular, the blood pressure was 100/60 The abdomen was negative There was massive, soft, pitting edema of both legs, including the thighs Retinal examination showed pallor and flame-shaped hemorrhages with absorbing centers

The laboratory reported 3.8 gm of hemoglobin (22.6 per cent) and a red cell count of 1.05 million The leukocyte count was 3000 with 67 per cent neutrophils (nonfilamented 13 per cent, filamented 51 per cent) 32 per cent lymphocytes, 3 per cent monocytes and 1 per cent eosinophils The blood film showed 5 nucleated erythrocytes per 100 leukocytes The mean corpuscular volume was 105 The mean red cell diameter was 11.2 microns (normal 7.4) with a range in size between 4.2 and 16.8 Aspirated sternal bone marrow, examined by Dr. F. W. Konzelmann, showed a predominance of nucleated erythrocytes (megakaryoblasts and macroblasts) and hypersegmentation of the nuclei of the neutrophilic leukocytes There was no free acid after histamine stimulation in the gastric juice An electrocardiogram showed low voltage in Leads I, II and III Serum cholesterol was 162 mg per 100 cc. (67 per cent in ester form) Total serum protein was 6.87 gm per 100 cc with a normal albumin/globulin ratio The basal metabolic rate was plus 4 per cent after ten days of liver therapy The urinalysis was normal The blood Wassermann was negative

The patient tolerated an intramuscular injection of 1 cc of liver extract (reticulogen, Lilly) The following day 9 cc was injected (total of 200 units with 100 mg of thiamine hydrochloride) His chest pain disappeared in four days and he was able to be out of bed

excess of basic requirements in order that a normal condition be maintained and a reserve supply be stored in the body. The amount of effective substance required to produce these results varies considerably in different patients. The condition of the individual patient is the final criterion. Other things being equal, more anti-anemic substance will be required if the patient is old, if he has arteriosclerosis or other disease, or suffers from an infection. In some patients absorption of liver, stomach desiccate, or yeast, given orally, is defective and no adequate response will occur until liver is given parenterally. In others there may be an associated deficiency of iron and a normal state will not be attained until iron is given as well. In patients with changes in the nervous system, complete relief of symptoms may never occur but treatment with large doses of anti-anemic substance must be continued for a long time for, with patience and persistence, some improvement will take place in most cases"*

Liver—The establishment of the anti-anemia unit of liver extract (USP) has brought order out of chaos caused by many preparations with various methods of manufacture. Intramuscular treatment is to be preferred to oral therapy because of greater effectiveness and economy for most patients. When the patient can be taught to give the injections, the cost will not exceed 5 cents per unit. Although by definition, 1 unit USP per day produces a maximum response, it is customary to use larger doses in anemic patients during the first two months. Massive initial doses (see Case IV) have been advocated with the hope of rapidly correcting the tissue deficiency of the anti-anemia factor.

The following program has proved satisfactory for uncomplicated cases in the initial or recurrent stage of relapse: 15 units USP intramuscularly (upper outer quadrant of buttock) daily for three days and then weekly until the erythrocyte count reaches 4.5 to 5 million per cu mm (usually about seven weekly doses). The management of patients with moderate or marked posterolateral sclerosis will be considered below.

For *maintenance therapy*, a dose of 15 units every four weeks is usually adequate. Blood examinations (hemoglobin, red cell count and hematocrit for calculation of the mean corpuscular volume) should be carried out at the end of the third and fourth and the fifth or sixth months of treatment to determine whether this dose is adequate to maintain a normal blood. Subsequently, blood counts at intervals of three to six months are usually sufficient unless symptoms recur or other diseases develop. Patients must understand that this substitution

* Wintrobe, M. M. Clinical Hematology. Philadelphia, Lea & Febiger, 1942.

therapy must be continued as long as they live. Some cases require 30 or even more units every four weeks. Intercurrent infections or toxemias increase the amount of liver needed. An inadequate diet may be responsible for the large doses required by some patients. Infrequently a poor therapeutic response is associated with local inflammatory reactions at the site of intramuscular injections (see Case III).

Severe untoward reactions to intramuscular injections of liver extract are infrequent. Local pain and tenderness, flushing of the upper part of the body, and a sensation of faintness are the most common complaints. Less often fever and local induration, which persists for days, occur. Injections should be continued because these reactions usually cease after a few weeks. An anaphylactic type of reaction is very rare, however, erythema, urticaria, tachycardia, hypotension, angioneurotic edema and asthma can be terrifying. A hypodermic injection of 0.5 cc of 1:1000 epinephrine hydrochloride solution should be immediately available whenever liver is injected. In some instances it seems probable that the intramuscular injection may have inadvertently entered a small vein. Allergic reactions are more likely to occur after a period of neglected treatment or in patients receiving injections at intervals of two or more weeks. Small doses (0.125 cc) repeated every thirty to sixty minutes will avoid serious reactions. These cases may tolerate small doses three times a week but reactions often recur as soon as the interval between doses is lengthened again. Changing to extract marketed by another manufacturer may not avoid the untoward symptoms. Some evidence suggests that the sensitivity is to some ingredient used in all liver extracts rather than to the animal species of liver. Many commercially available extracts are derived from a mixture of pig and cow livers. An extract prepared from the liver of horses is available and may be useful in some patients. Oral liver extract may be tried but sensitivity reactions may follow ingestion also. The oral use of the dried, defatted gastric mucosa of the pig (ventriculin NNR) in doses of 10 gm, four times a day (or once daily as a maintenance dose), or brewers' yeast powder in doses of 30 to 60 gm daily may solve this therapeutic problem.

Hydrochloric Acid—In recent years hydrochloric acid has been neglected in the treatment of pernicious anemia. Some patients never have any gastrointestinal symptoms and many entirely healthy older people have achlorhydria gastrica. In fact, some asymptomatic persons with achlorhydria suffer with indigestion when they take hydrochloric acid with their meals. In many cases of pernicious anemia the gastrointestinal complaints are entirely relieved by the administration of liver extract. Theoretically and from the point of view

of general nutrition over a period of years, it seems desirable to prescribe 2 to 4 cc ($\frac{1}{2}$ to 1 teaspoonful) of dilute hydrochloric acid USP in a full glass of water or fruit or vegetable juice, to be sipped through a glass straw throughout the course of large meals (not with a sandwich and coffee lunch) in the manner in which some people drink small amounts of water at frequent intervals during a meal. If this large volume of a sour drink is very unpleasant to the patient, the same effect may be obtained at slightly greater expense from 3 to 6 capsules containing 0.5 gm each of glutamic acid hydrochloride, taking half of the capsules before and half after the meal.

Rest—Anemic cases are often ambulatory and they may be allowed as much activity as their individual effort limitation will permit. Patients with an erythrocyte count of 1 million per cu mm or less, and those suffering with pneumonia and other infections, congestive heart failure, angina pectoris, etc. should be confined to bed except for periods in a chair two or more times daily to minimize the danger of venous thrombosis and pulmonary congestion.

Fluid—Neither limitation nor forcing of fluids is necessary unless demanded by complicating conditions such as infections or cardiovascular disorders.

Diet—The needs of most patients with pernicious anemia do not differ from those of other persons of similar age, general health and physical activity. However, since dietary habits are so frequently peculiar, the physician must inquire specifically into the patient's meals and advise, in understandable language, an adequate intake of protein, vitamins and minerals, giving due consideration to the demands of coexistent disorders and to the patient's impressions of the unsuitability of specific foods. Insistence on obtaining satisfactory false teeth for adequate chewing is often important. General dietary instructions are seldom superfluous, the inclusion of milk, vegetables, fruits, eggs, meat or cheese or fish or fowl, whole grain cereal and bread, and butter in the daily diet is usually desirable.

Vitamins—An adequate intake of all vitamins in the form of natural foods is always indicated and merits special attention in old people since they often live on a high carbohydrate diet. Unless specific clinical evidences of coexistent avitaminosis are present, the administration of large amounts of the synthetic vitamin fractions is not beneficial and may actually prove deleterious. If the B vitamins are prescribed, a concentrate of a natural material, such as yeast, whole liver, rice bran or wheat germ, is to be preferred to the highly potent but incomplete mixtures of the available crystalline vitamin B factors. In some patients supplementary amounts of vitamin C must be provided.

to obtain a therapeutic response to the exhibition of vitamin B. It has been suggested that the tendency of patients with pernicious anemia to relapse in the spring of the year is associated with a deficiency of vitamin C.

Iron—The majority of patients with pernicious anemia do not require the administration of iron. If malnutrition or chronic bleeding has been present, it is desirable to administer iron from the beginning of therapy. Ferrous sulfate, exsiccated U.S.P. X, 0.2 gm. three or four times daily before meals, is cheap, effective and usually well tolerated. If the hemoglobin level does not increase as the erythrocytes approach normal, medicinal iron is indicated.

Mouth Wash—Since symptomatic relief of the stomatitis is induced so rapidly by liver extract, local therapy is rarely required. The following prescription is soothing and cleansing.

Sodium bicarbonate,	
Sodium borate,	
Sodium chloride	aa 15 gm.
Oil of peppermint	
Misce.	q.s. flavor

Sig $\frac{1}{2}$ teaspoonful in a glass of warm water as a mouth wash three times a day after meals and at bedtime.

Transfusion—This is likewise rarely necessary because of the rapidity of the response to liver therapy. Transfusion of 500 cc. of whole, fresh or bank blood is indicated in patients with erythrocyte counts of less than 1 million per cu. mm. and in patients seriously ill with coexistent infections, such as pneumonia, toxemias, such as uremia and cardiovascular disorders, such as coronary artery disease. If due care is exercised in typing and cross-matching the patient's and the donor's cells and sera and in handling the blood, reactions are no more common than in other diseases. Red cells salvaged from the manufacture of plasma, suspended in normal saline solution and given intravenously within five days of donation are beneficial. In the rare instance of acute hemolytic anemia simulating pernicious anemia, serious hemolytic reactions may occur.

MANAGEMENT OF POSTEROLATERAL SCLEROSIS

The patient with pernicious anemia and moderate or marked evidences of degeneration of the posterior and lateral columns of the spinal cord requires more intensive and persistent therapy. The following program is both adequate and practical. Inject 200 units of liver extract U.S.P. intramuscularly during the first week (see Cases II and IV). Then give 50 units weekly until the erythrocyte count

reaches 45 million per cu mm. Continue injections of 30 units every one or two weeks until a satisfactory or apparently maximal (after one to two years) symptomatic relief of the neurological manifestations has been achieved. A permanent maintenance dose of 2 to 3 units daily is indicated. The intramuscular administration of thiamine hydrochloride in doses of about 10 mg three times a week should also be carried out during the first two or three months. The use of the less concentrated liver extracts is favored by some physicians, but the large volume of extract necessary to provide the required number of units of anti-anemia material makes their sole use both uncomfortable and impractical. Furthermore, most of the dilute liver extracts available differ chiefly in water content from the more concentrated preparations produced by the same manufacturers. Satisfactory results are obtainable with the highly concentrated liver extracts (see Case II). Brewers' yeast powder in doses of 30 to 60 gm daily by mouth or the ingestion of $\frac{1}{2}$ pound of liver several times a week will supply plentiful amounts of all the factors in the vitamin B complex.

A diet high in protein (60 to 80 gm daily with emphasis on animal protein) and carbohydrate (150 to 200 gm daily) is indicated. The injection of insulin in doses of 5 units three times daily before meals for several days has been advocated (Lewy) as a means of rapidly restoring liver function to normal.

Dilute hydrochloric acid should be administered with meals if at all possible. Clinical experience has favored the use of acid in the therapy of posterolateral sclerosis for many years, even before the importance of liver was recognized.

Urinary tract infection must be treated appropriately.

Physical therapy is important to facilitate the recovery of muscle function and coordination. Prescribe heat in the form of a lamp, heating pad or hot water bottle several times daily for periods of about twenty minutes, followed by light stroking massage and active exercise (assisted voluntary motion of involved muscles and joints if necessary). Encouragement, reassurance and help are of great importance. Furniture should be located about the room so that the patient may use the arms to aid himself in walking. The muscle re-education program needed resembles that followed in luetic tabes dorsalis.

OTHER MACROCYTIC ANEMIAS

Criticism of the promiscuous use of liver extract in the treatment of any anemic patient without adequate, although simple, diagnostic *y* has been frequent and is justified. Pernicious anemia requires

continuous treatment for the duration of the patient's life. The rapid symptomatic improvement which follows liver therapy in pernicious anemia eliminates the diagnostic abnormalities of the blood and, without a proven diagnosis, the patient is more likely to neglect treatment. The resultant relapse of pernicious anemia may be associated with irremediable neurologic changes. However, macrocytic anemia occurs in numerous other disorders and liver extract is indicated and valuable, when employed with understanding, in many of these. Whenever a megaloblastic bone marrow is found, liver extract is indicated. When normoblastic marrow exists, liver therapy is not specific but it may be beneficial. In macrocytic, hypochromic anemias iron medication is also indicated.

Pregnancy—Among the macrocytic anemias one of the more common is the macrocytic anemia of pregnancy. Iron deficiency (hypochromic-microcytic) anemia is much more common in pregnancy but a macrocytic type occurs not infrequently, especially in malnourished women. Allowing for the physiologic increase in plasma volume which reaches a maximum of about 25 per cent at the sixth month of gestation, macrocytic anemia is characterized by an erythrocyte count of less than 3.5 million, a color index greater than 1.1 and a mean corpuscular volume greater than 97. As is the case in other macrocytic anemias, the variation in size of the erythrocytes is less marked than in primary pernicious anemia i.e., the diameters are seldom as small as 3 or as large as 16 microns. Leukopenia and paresthesias are unusual. A general dietary deficiency is usually found and liver extract therapy alone is not rapidly and completely effective. A diet containing 50 gm. or more of protein daily in the form of meat, eggs, milk and cheese is necessary.

Carcinoma of the Stomach—Macrocytic anemia is not common in this condition but the clinical features may closely simulate pernicious anemia for several years until the condition is inoperable. Among 1014 cases of pernicious anemia at the Mayo Clinic, 17 per cent were found to have cancer of the stomach and 0.39 per cent benign polyps of the stomach. It is a wise clinical practice to make an x-ray examination of the upper gastrointestinal tract of all patients suspected of having pernicious anemia who do not conform to the common constitutional type (blue-eyed blonds with early graying of the hair of the head, sparse body hair and eunuchoid build) or whose gastrointestinal symptoms do not respond promptly to liver therapy. In a patient receiving liver therapy an unexplained change to a hypochromic type of anemia also demands a search for cancer.

Gastrectomy.—This procedure, even when the entire stomach is re-

moved, rarely results in macrocytic anemia (none among fourteen total and 460 partial gastrectomies at the Mayo Clinic) but frequently is followed by hypochromic anemia. Since it is now known that the intrinsic factor is formed in the fundal and cardiac portions of the human stomach and since patients rarely survive many years after a total gastrectomy, the rarity of macrocytic anemia is not surprising.

Intestinal Anastomoses—Extensive resections of the small intestines, especially where a blind loop of bowel is present, may be followed by very severe macrocytic anemia and usually other manifestations of nutritional deficiency. This anemia usually responds to parenteral liver therapy but much larger doses are necessary than in pernicious anemia (about 50 units weekly). Resection of the blind loop may relieve the macrocytic anemia.

Malnutrition (Extrinsic Factor Deficiency)—This condition, unassociated with other manifestations of nutritional deficiency, is rare. The deleterious effect of an inadequate diet on cases of mild or subclinical pernicious anemia has already been mentioned. The important therapeutic measure is the provision of an adequate diet, especially of the extrinsic factor, such as 2 or more ounces of brewers' yeast powder or autolyzed yeast (Vegex) daily. The powder is best administered in a milkshake, Vegex may be mixed with cheese and eaten in a sandwich.

Liver Disease—Mild degrees of macrocytosis associated with very slight depressions of the hemoglobin and erythrocytes are frequent in both acute hepatitis and the more chronic cirrhotic disorders of the liver. Some of the increase in size of the erythrocytes may be related to the decreased osmotic pressure of the hypoproteinemic blood plasma commonly present. An actual deficiency in the liver anti-anemia factor may exist. Parenteral liver extract, 10 to 20 units three times a week, is valuable in the general management of patients with disease of the liver.

Pellagra—This nutritional deficiency state is usually associated with a hypochromic anemia. Liver extract has long been of recognized value in the treatment of pellagra and is superior to nicotinamide alone, in that liver provides all of the factors of the vitamin B complex.

Sprue (and Idiopathic Steatorrhea)—Macrocytic anemia is found in some cases (usually the severe and prolonged ones). Liver extract, 10 to 20 units daily parenterally together with an adequate diet, will correct the anemia and benefit the deficient intestinal absorption in these patients.

Myxedema—Macrocytic anemia is less frequent than hypochromic or normochromic anemia in hypothyroidism. When it occurs, cor-

rection of the myxedema with desiccated thyroid is necessary before a full response of the anemia can be obtained with liver extract. A few cases of severe macrocytic anemia associated with pituitary disease have been reported, liver therapy is indicated in such cases.

Fish Tapeworm (*Diphyllobothrium latum*)—The possible coincidence of this infestation with primary pernicious anemia has been favored because this tapeworm is most common in the Scandinavian racial group in which pernicious anemia is also frequent. Liver therapy will correct the macrocytic anemia, in some instances the expulsion of the worms has been followed by a reticulocyte response and relief of the anemia without liver therapy.

Miscellaneous—Macrocytic anemia exists at times in a number of conditions such as leukemia, myelophthisic anemia, diffuse osteosclerosis, agnogenic myeloid metaplasia of the spleen, aplastic anemia, uremia and may be present several days after an acute massive hemorrhage. In acute hemolytic anemias or hemoglobinurias the macrocytosis may be quite definite, but the marked icterus or dark urine and the severity of the illness avoids confusion with pernicious anemia. Liver extract administered parenterally is often beneficial in serious and chronic infections such as chronic ulcerative colitis, osteomyelitis, etc. and in many conditions in which a parenteral form of vitamin B complex therapy is desired.

SUMMARY

Primary pernicious anemia is a disorder involving three systems—neurological, gastrointestinal and hematopoietic.

Paresthesias of the extremities or glossitis and dyspepsia suggest the diagnosis of primary pernicious anemia. Pallor may be absent and even anemia may be very slight. A clean, smooth and pale or red tongue and impaired sense of joint position are the important physical findings.

A diagnosis of primary pernicious anemia requires the laboratory demonstration of a macrocytic anemia and achlorhydria gastrica after histamine stimulation. In questionable cases, sternal aspiration is indicated in search of hyperplastic and megaloblastic marrow.

Treatment consists of adequate intramuscular doses of liver extract, for maintenance an average of $\frac{1}{2}$ to 3 units U.S.P. daily should be administered for life at intervals of one to six weeks. Patients with combined degeneration of the spinal cord require large doses. Untoward reactions are infrequent. Dilute hydrochloric acid an adequate diet and, in some cases, ferrous sulfate are also important measures. Liver therapy is also valuable in the treatment of some other macrocytic anemias.

THE RATIONAL ENDOCRINE THERAPY OF MENSTRUAL DISORDERS

A. L. RAKOFF, M.D.*

THE increasing number of potent gonadotropic and gonadal hormones has furnished the physician with an array of specific therapeutic agents which can be added to the old stand-bys of rest, diet, emotional readjustment, thyroid extract, and curettage for the treatment of functional menstrual disorders. The brilliant results that are sometimes achieved with these products and their acknowledged biologic potency attest to their potential usefulness, while the disappointing or even untoward results which are not infrequently reported, emphasize the problems and limitations of the treatment of menstrual dysfunctions with sex endocrine preparations. Indeed, it is safe to say that the introduction of hormonal therapy has not simplified the treatment of many gynecologic conditions, but has made apparent to the physician the necessity for a better appreciation of their physiologic basis, the necessity for accurate diagnosis, accurate knowledge of the actions of the hormones and care in their use.

It cannot be overemphasized that menstrual dysfunction is a symptom, not a disease, and may result from a great number of causes. The doctor's first responsibility is to determine whether there are any local organic abnormalities, particularly neoplasms, and then to evaluate the possible influence of the various clinical findings on the physiologic mechanism of menstruation. The need for thorough pelvic examination, and diagnostic curettage when in doubt, is all the more necessary, if endocrine therapy is to be employed in the light of recent warnings¹ that injudicious hormonal treatment may conceal malignancy.

When local and systemic organic disease have been ruled out as factors in disturbances of menstruation the physician still faces a difficult diagnostic problem, for it is frequently not possible to determine from the clinical manifestations the nature of the physiologic disturbance. It may be some dysfunction inherent in the pituitary-ovarian uterine mechanism or it may represent the effects of other

* Director of the Endocrine Laboratory, Jefferson Hospital, Assistant Demonstrator in Obstetrics, Instructor in Gynecology, Jefferson Medical College.

functional abnormalities upon this mechanism, such as dysfunctions of the thyroid, adrenal and other glands of internal secretion, obesity, malnutrition and diseases of metabolism, or emotional and psychic disturbances. In those cases in which these latter causes are discovered and corrected, lasting improvement in the menstrual disorder commonly follows. In a large proportion of the instances, however, some abnormality of pituitary or ovarian function exists for which no exogenous factor can be discovered. It is in this group that sex endocrine therapy finds its most rational application. However, because of their potent biologic actions the sex hormones are not infrequently employed as an adjunct to other types of treatment or to produce some specific effect.

DIAGNOSTIC AIDS

The rational use of sex hormone therapy implies the necessity for making an etiologic diagnosis. This is particularly important since many of the clinical manifestations of menstrual dysfunction such as amenorrhea, menorrhagia or irregular bleeding can be associated with various types of sex hormone patterns. Unfortunately, we do not have any simple test for determining pituitary and ovary function. On the other hand, certain diagnostic aids are available. Their proper use has done much to place sex hormone therapy upon a rational basis. The information thus obtained must be interpreted in the light of the normal physiology of the sex endocrine cycle (Fig. 44).

1. Study of the Endometrium—Histologic study of the endometrium obtained by curettage is the most prevalent diagnostic procedure employed by the gynecologist. It depicts the end result of the effect of ovarian activity on the endometrium since the last bleeding. Although most commonly employed to rule out local abnormalities of the uterus, or as a therapeutic procedure to control bleeding, from careful histologic study of the tissue one can obtain qualitative evidence of the sum total of estrogenic and progesterone effect. It is particularly useful in determining whether or not there has been a functioning corpus luteum.

Provided that the endometrium is normally responsive, abnormalities of the endometrial pattern can be correlated to a considerable degree with the type of ovarian dysfunction, on the other hand it gives no direct evidence of cyclic variations in the ovary or gonadotropic activity. Whether endometrial biopsies or urine and blood hormone assays afford the better information is a moot point, undoubtedly, together, they afford the most information.

In recent years, endometrial biopsy by suction curettage has been done as an office procedure in suitable cases, namely in patients in

whom there is no suspicion of infection, and in whom the cervix is easily accessible and not too rigid. If properly done, sufficient tissue for adequate examination can be obtained without much discomfort

THE FEMALE SEX ENDOCRINE CYCLE

Fig 44

to the patient and at a minimum of time and expense. Those who use the method, however, must thoroughly acquaint themselves with the technic and its possible dangers.

2. Vaginal Smears—Cytologic study of the human vaginal epithelium as seen on vaginal smears stained by special methods affords a simple, convenient and inexpensive method for determining estrogenic effect and cyclic ovarian changes. From it, one can easily pick up gross ovarian deficiencies and by observing the day-to-day changes, it is possible to determine fluctuations in estrogenic activity and often the probable date of ovulation.² Certain regressive changes are sometimes taken as an indicator of a corpus luteum effect, the accuracy of the latter diagnosis is at present questionable. The effectiveness of therapy can often be easily followed by the vaginal smear method. Considering the amount of useful information which can be obtained for the effort expended, the vaginal smear is not used by the general practitioner or the gynecologist nearly so much as it should be.

3. Hormone Assays—Direct determination of the excretion of the gonadotropic and gonadal hormones in the urine yields quantitative data concerning hormonal activity at the time. Although such tests are time-consuming and somewhat expensive, they yield the most direct evidence of endocrine function. Indeed, the biologic gonadotropic assay is the only means we have available for determining gonadotropic activity. This becomes of primary importance in deciding whether a given syndrome is due to a primary ovarian or a primary pituitary dysfunction, and in deciding whether rational gonadotropic therapy is indicated.

The hormones which can be determined in this manner are as follows: (a) Gonadotropic hormone. Biologic assay. (b) Estrogenic hormone. Biologic assay. (c) Progesterone. Clinical determination of its excretion product, pregnandiol (sodium pregnandiol glycuronide). (d) Androgens. Biologic assay can be done but is difficult. Chemical determination of the 17-ketosteroids often reveals comparable information. In the female these are believed to originate in the adrenal cortex.

The diagnostic value of such assays and the normal values of the hormone patterns commonly observed in various dysfunctions have been discussed in more detail in an earlier clinic.³

PRINCIPLES OF TREATMENT

Specific endocrine therapy of menstrual disorders can be divided broadly into the following categories:

1. Substitution Therapy—By this is meant the administration of hormones which directly effect the end organ and for which a deficiency exists in the body. Not infrequently substitution therapy is given in such a fashion in the hope that it will eventually prove to be "stimu-

lation" therapy by giving the "endocrine wheel a spin," such as sometimes happens after substitution therapy for amenorrhea. When substitution therapy is employed the following *disadvantages and limitations* must be borne in mind

(a) When the ovarian hormones are administered for substitution therapy, all hope for ovarian function must be given up for the time being, that is, while large dosages of estrogen are being administered it is not likely that ovulation will occur. This is of particular significance in the treatment of young women who are desirous of pregnancy.

(b) The possibility of inhibiting the pituitary by too vigorous or persistent administration of estrogens must be considered, this is a moot question.

(c) There is considerable evidence pro and con concerning possible deleterious effects of prolonged administration of estrogens and progesterone on the ovary.

(d) The results of substitution therapy cannot be expected to carry over after treatment is discontinued, although sometimes they may.

2 Stimulation Therapy.—At the present time, there is no accepted and proven method for stimulating gonadotropic function of the pituitary. Low dosage irradiation to the pituitary or to the pituitary and ovaries has been advocated by a number of workers^{4, 5} as a method for the treatment of amenorrhea, anovulatory sterility and various menstrual dysfunctions. It is presumed that the irradiation stimulates the structures treated, but this is open to question. The physiologic effects of this type of therapy are not known nor are the possible harmful effects immediate and remote, although no untoward clinical effects have been reported.⁶

It is believed by many that the cyclic administration of estrogens and progesterone may result in a stimulating "back effect" upon the pituitary. This theory is generally used to explain the continued good results which occur in some cases after substitution therapy has been withdrawn.

The commonest type of direct stimulation therapy is the use of gonadotropic hormones to stimulate the ovary. From the theoretical standpoint, this type of treatment offers many possibilities particularly in the treatment of functional sterility, unfortunately however, gonadotropic therapy presents many difficulties and must still be considered in the stage of clinical trial.

3 Inhibiting Effects.—The gonadal hormones are commonly believed to inhibit gonadotropic function of the pituitary, lactogenic hormone and possibly other pituitary hormones. These inhibiting influences

may be employed with benefit in the treatment of certain menstrual dysfunctions

4 Specific Pharmacologic Effects—The sex hormones are sometimes administered to produce some specific biologic effect even though their use may be otherwise unphysiologic, thus estrogens may be given to children with gonococcal vulvovaginitis to develop a thick vaginal mucosa and increased vaginal acidity, or androgens may be given to stop functional bleeding by its direct effect on the endometrium. The dangers of this type of treatment are that other undesirable results may be produced, and should usually be employed only as a temporary expedient.

GONADOTROPIC HORMONES

The following types of gonadotropic hormones for therapeutic use are available

1 PITUITARY GONADOTROPIC HORMONES—These are prepared from the pituitary glands of animals, usually sheep, and contain both the follicle stimulating and luteinizing fractions. Because of the difficulties in purification, it is probable that small amounts of other pituitary hormones as well as other proteins are present.

2 EQUINE GONADOTROPIC HORMONE—During a short phase of early gestation the pregnant mare produces a gonadotropic hormone which can be recovered in high concentration from the serum, but is not excreted in the urine. Unlike the human chorionic gonadotropin this hormone is rich in the follicle-stimulating as well as luteinizing fraction, indeed in primates its action is chiefly follicle-stimulating.

3 CHORIONIC GONADOTROPIN—During human pregnancy the placenta produces huge amounts of a gonadotropic hormone which is entirely luteinizing in its action. Commercial preparations can be conveniently prepared from human pregnancy extracts.

4 COMBINED PITUITARY AND CHORIONIC GONADOTROPINS ("SYNERGISTIC GONADOTROPINS")—A commercial preparation* containing a mixture of chorionic gonadotropin and pituitary gonadotropin is being used on the basis of evidence which indicates that such mixtures have a synergistic effect on the ovary. In rodents greater follicular stimulation and functional activity results from such a combination than would be expected from the additive effects of each alone.

General Indications—Gonadotropic therapy is indicated only when there is good clinical or laboratory evidence to indicate a pituitary gonadotropic deficiency. It has been used to stimulate ovarian function whether it be for the correction of the systemic manifestations of hypogonadism, amenorrhea, anovulatory sterility, or functional bleeding. However, it will be readily appreciated that if normal or excessive gonadotropic function is already present these hormones may

* Synapoidin (Parke-Davis).

exert deleterious effect on the gonads.⁷ Furthermore, a "normal" response cannot be expected from diseased or abnormal ovaries and indeed untoward or unpredictable effects may follow under such circumstances. When employed to stimulate the ovaries, every attempt should be made to imitate the normal physiologic pattern for follicular stimulation, no matter which type of preparation is chosen. Injections should be started early in the cycle and continued to the mid-cycle or possibly into the third week, but they should never be given through the entire cycle because of the dangers of producing unruptured follicular cysts, markedly enlarged ovaries or ovarian hemorrhage. Even when given cyclically their administration should not be continued for more than three months without an equal rest period, not only because of the dangers already mentioned but because of the possibility of producing antigonadotropins.⁸

Chorionic gonadotropin is rationally indicated only during the last half of the menstrual cycle and is used to stimulate or maintain corpus luteum function. Chorionic gonadotropin was the first of the gonadotropic hormones to be commercially available and in the early days much was expected from it. Clinical evaluation, however, has proved very disappointing. There has been considerable reason to question whether chorionic gonadotropin exerts any influence at all on the ovary which is not normally stimulated earlier in the cycle. It has also been suggested that under certain circumstances it may produce atretic follicles. Its use in the treatment of menstrual dysfunctions has been disappointing.

Various commercial preparations of chorionic gonadotropin are standardized according to the international standard as adopted by the League of Nations. A similar standard is available for equine gonadotropins but unfortunately a number of the commercial firms have adopted their own units and thus has caused much confusion. A similar difficulty exists with regard to the potency of the pituitary gonadotropins. Furthermore it is almost impossible to compare the relative gonadotropic potency of pituitary, equine and "synergistic" gonadotropins, particularly with regard to the human ovary.

The gonadotropic preparations are proteins and are, therefore, capable of inducing local and systemic reactions in sensitive individuals. Local reactions of varying intensity are quite common with all of these preparations but occur less frequently with chorionic gonadotropin. Systemic anaphylactic reactions are most common with the equine gonadotropins, particularly in patients who are sensitive to horse serum. By skin testing or conjunctival testing before injection, hypersensitivity can frequently be detected.

Amenorrhea—Gonadotropic stimulation may be tried in amenorrheic patients with gonadotropic failure. Although occasionally such a patient may have other evidences of pituitary deficiency, it is usually not possible to make an etiologic diagnosis except by means of a urinary gonadotropic assay. This type of stimulation is particularly indicated in young women with primary amenorrhea who have failed to undergo sexual maturation. The percentage of successful results with this treatment is not high, particularly if the cases are not properly chosen, but when effective is often more permanent than with substitution therapy, certainly it is a more physiological and rational approach^{9, 10}

Any of the follicle-stimulating gonadotropins may be employed for this purpose. The author generally employs the following dosage schemes

1 *Pituitary Gonadotropin*—Fifty to 250 international units intramuscularly two to three times a week for the first two weeks of each month. Repeat for a total of three months. A rest period of at least three months is given before repeating the course.

2 *Equine Gonadotropin*—Same plan as above, employing 200 to 400 I U (or its equivalent) at each dose, intramuscularly.

3 *"Synergistic" Gonadotropin*—Ten to 15 "synergy units" at each injection following the same plan.

Anovulatory Sterility.—Gonadotropic hormones find their widest field of application in the treatment of impaired sterility. Unfortunately this kind of therapy is often indiscriminately used in sterile women without adequate study to determine whether there is actual failure of ovulation, let alone determining whether there is a gonadotropic deficiency. Considerable controversy exists as to whether the gonadotropic preparations we now have available are capable of inducing ovulation in the human ovary in the absence of normal pituitary stimulation, and the validity of the clinical experiments which have been performed in this regard have been subjected to much criticism. On the other hand, many conservative workers believe that in properly chosen cases gonadotropic stimulation has afforded the additional "boost" necessary to result in ovulation and successful pregnancy.

The same dosage scheme suggested for the gonadotropins in the treatment of amenorrhea may be employed. On occasion larger dosages or more frequent injections may be given in the second week of the cycle. Also intravenous injection of as much as 2000 I U of equine gonadotropin may be given intravenously on the tenth to the twelfth day of the cycle but this is particularly hazardous not only because of the possibility of severe anaphylactic reaction but because

of marked ovarian enlargement which may follow. We have observed ovarian hemorrhage requiring operation following injudicious therapy of this kind.

Functional Bleeding—In some cases of menometrorrhagia, gonadotropic therapy has yielded excellent results and occasionally has succeeded where androgens have failed, in other instances the administration of gonadotropins has been of no use whatsoever. In our experience the patients with low or absent gonadotropins and estrogens are most likely to obtain a good result and will often stop bleeding after two or three injections. In the beginning it is usually necessary to give the injections every second or third day for two to three weeks after which the same dosage schedule given above for the treatment of amenorrhea can be followed.

In young women with functional menorrhagia beneficial results are occasionally obtained with chorionic gonadotropin in dosages of 200 to 300 I U given two to three times weekly during the last two weeks of the cycle.¹¹

Dysmenorrhea—Follicle-stimulating gonadotropins are usually of no value in the treatment of primary dysmenorrhea. Chorionic gonadotropin given during the last two weeks of the cycle does not often yield favorable results.

ESTROGENS

General Indications.—Estrogenic hormones are logically indicated in those menstrual disorders which are associated with a primary ovarian deficiency. This type of treatment is substitutional in character and, therefore, the results obtained are frequently only of temporary value. Under certain circumstances, however, such substitutional therapy may induce effects which may be quite permanent and quite worthwhile. An example is the induction of sexual maturation with the development of the secondary sex characteristics and growth of the uterus in young women with infantilism due to a primary ovarian deficiency.

Estrogens may also be employed to inhibit the pituitary if there is excessive gonadotropic function as the cause for the menstrual disorder. Primary hypergonadotropism, however, is uncommon. It may be encountered early in basophilic and eosinophilic tumors of the pituitary but usually excessive gonadotropic function is secondary to an ovarian deficiency.

Estrogens are not infrequently employed in the treatment of functional uterine bleeding on an empiric basis, on the theory that estrogens will "build up" the endometrium and thus stop the bleed-

ing Although this may be beneficial in an atrophic type of endometrium, its value in patients with a hyperplastic endometrium is questionable and its use open to criticism

Estrogens also may be employed if given in fairly large doses to inhibit ovulation where this is considered desirable, such as in the treatment of certain types of dysmenorrhea, premenstrual tension and unusual moulmina.

The physician today has a large choice of natural and synthetic estrogens from which he may choose These differ in potency, oral effectiveness, toxic effects and expense It is difficult to evaluate their relative effectiveness, advantages and disadvantages It is therefore best for one who only occasionally uses these hormones to become familiar with a few representative members so that he may better know just what response to expect.

Amenorrhea and Hypomenorrhea.—Estrogens are quite commonly used to bring on bleeding in patients with primary or secondary amenorrhea or to “regulate” the periodicity and amount of flow in patients with infrequent or scanty menses Treatment of this type is not always justifiable If history and physical examination including pelvic examination fail to reveal any demonstrable endocrine cause for the trouble, it then becomes necessary to decide whether the deficiency is primarily one of inadequate gonadotropic stimulation, a primary functional disorder of the ovaries, or a uterine defect In the case of a primary ovarian hypofunction, substitution therapy with estrogens or estrogens and progesterone may be attempted¹² This is particularly worthwhile if there are systemic manifestations of hypogonadism On the other hand, if the young woman is normally developed, the induction of bleeding by substitution therapy may be only of psychological benefit, occasionally however, it is true that inducing a number of bleedings by substitution therapy may start normal cycling

If estrogens alone are to be used, the hormone should be given in moderately large dosage by injection (10,000 to 50,000 I U twice weekly) or orally (diethylstilbestrol 0.25 to 1.0 mg daily or its equivalent) for a period of three weeks and then withdrawn Bleeding most commonly occurs about one week following estrogen withdrawal There may, however, be considerable variation depending upon the hormonal status of the individual and their sensitivity to the hormone Occasionally patients will even “break through” with bleeding during the time that the hormone is being administered Under such circumstances, the estrogen is stopped until the flow is over and started again

If no bleeding has occurred within ten days after estrogen is withdrawn, it is usually wise to begin again, possibly with a higher dosage. If no bleeding can be induced by the cyclic administration of estrogens alone, the addition of large doses of progesterone (see below) during the last few days of treatment may be beneficial. Failure to obtain success after a reasonable trial on substitution therapy, justifies further investigation including diagnostic curettage.

Sterility—It must be remembered that the administration of estrogens is not rational therapy for the treatment of sterility. It may be used as a temporary device for the treatment of associated hypoplasia of the uterus or amenorrhea if the latter are due to an ovarian deficiency. During the course of estrogen administration, if large dosages are being employed, it is probable that any attempt at ovulation will be inhibited. Also to be considered are the possibility that the prolonged administration of estrogens may inhibit the pituitary or ovary or both for sometime, although as already stated this is a debatable point.

Functional Bleeding—It is believed that most types of functional uterine bleeding are due to some abnormality in the cyclic production of estrogens or in their metabolism. During the normal menstrual cycle, estrogens rise progressively during the follicular phase to reach a peak shortly after ovulation (Fig. 44). This is followed by a fall for several days and then a second rise as the corpus luteum becomes functionally active. This second peak is reached about five or six days before the expected menses and then is followed by an abrupt fall which is believed to precipitate bleeding. Any condition which will result in an irregular estrogen curve may produce abnormal bleeding.

From this standpoint, the continued administration of high dosages of estrogen should prove useful in controlling bleeding and indeed, this is clinically often the case. It is also often of benefit in controlling the postovulatory bleeding which occurs in some women. However, this type of treatment can hardly be said to correct the underlying defect in all or even most types of functional bleeding. It is most helpful in the treatment of bleeding associated with an atrophic endometrium in young women when the latter is due to a primary ovarian defect. If, on the other hand, the bleeding occurs from a hyperplastic endometrium, then the administration of more estrogen may precipitate more troublesome bleeding at a later date. This applies also to all types of bleeding associated with high estrogen levels or prolonged production of normal estrogen concentrations such as may be encountered with follicular cysts, corpus luteum cysts and that clinical syndrome known as "metropathia haemorrhagica".

This author particularly disapproves of the use of enormous dosages¹⁸ of estrogens as a device to stop bleeding of any etiology even though it may be used only as a temporary measure. Until more is known concerning the direct and remote effects of such large dosages of estrogenic hormones upon human physiology, this type of therapy should be considered only from the standpoint of clinical investigation. Moreover, its possibilities in obscuring the etiology of the bleeding are particularly dangerous.

Dysmenorrhea.—It is well known that dysmenorrhea is relatively uncommon in anovulatory cycles. On this basis, the administration of sufficient estrogen to inhibit ovulation has proved to be dramatically successful in a large percentage of cases. However, the benefit thus derived does not usually continue after hormonal treatment has been stopped. For this reason it is questionable whether one is justified in employing it for more than two or three months at a time, if that long, until we know more about the ultimate effects of the continued uses of estrogens. Where such treatment is to be employed the estrogen is started on about the fifth day of the cycle in a dosage of 0.5 to 1.0 mg of stilbestrol daily or its equivalent. It is continued until the twenty-first day of the cycle. In cycles in which ovulation has been inhibited by this means, there is frequently a marked reduction in associated symptoms of premenstrual tension, migraine, depression, and occasionally in more unusual manifestations which may be associated with the menstrual phase such as purpura, ulcerations of various mucous membrane, marked edema, and the like.

Contraindications.—There can be no question whatsoever that the indiscriminate and injudicious uses of the estrogens has resulted in a marked increase in gynecologic disorders.¹ This is partly due to the fact that these potent hormones are often being employed without proper diagnostic investigation, without adequate pelvic examination at frequent intervals and without adequate supervision. In the treatment of menstrual disorders particularly, estrogens should not be employed for treatment until every reasonable effort to exclude neoplasm or other local organic factors as a cause has been made. Very frequently, particularly in the age group beyond 30, this will involve in addition to careful pelvic examination, a diagnostic curettage. Although it has never been proved that estrogens are carcinogenic for the human, the fact that they stimulate certain types of cancers in lower animals raises the question as to whether it is wise to employ estrogens in women with family histories of genital or breast malignancies.

Prolonged use of estrogens in young fertile women is to be dis-

couraged because of possible inhibiting effects upon the ovary and pituitary. The unphysiologic or contraphysiologic use of estrogens frequently results in further disruption of the menstrual cycle and other unfavorable effects.

Some women may exhibit symptoms of toxicity, particularly nausea, headache and general malaise, following the use of the synthetic estrogens. Occasionally, patients may note an allergy to the oil in which the hormone is dissolved, or develop small lipomas at the sites of injection.

Finally, it must be emphasized that estrogens should be given cautiously to women for the treatment of the menopausal syndrome and only when really required. Every effort should be made to keep the dosage below that which might result in uterine bleeding. Once bleeding has started, the responsibility for differentiating between malignancy and estrogen withdrawal bleeding belongs to the physician, and not infrequently presents a very confusing problem.

PROGESTERONE

General Indications—Progesterone, the hormone of the corpus luteum, acts upon the endometrium which has been primed by estrogen during the follicular phase to produce a secretory or pregravid endometrium. If pregnancy does not occur the corpus luteum degenerates with a failure of estrogen and progesterone and consequent menstruation. If pregnancy does occur, progesterone acts as a "uterine sedative." It is also necessary for the normal metabolism of the estrogens.¹⁴

The early clinical results with progesterone in the treatment of functional bleeding, dysmenorrhea and threatened abortion were rather disappointing. Today with the availability of larger dosages of the synthetic hormone and a better understanding of its action, progesterone has a very definite but not too large field of application in the treatment of menstrual disorders. It is also now quite popular as an aid in the treatment of amenorrhea, since Zondek⁵ has shown that bleeding will occur within a few days following the administration of large dosages of progesterone to an estrogen-primed endometrium. Smaller dosages of progesterone usually delay menstruation. It is also becoming increasingly apparent that in order to obtain the typical progesterone response in the treatment of corpus luteum deficiencies in the non-pregnant or in the pregnant woman, it is frequently necessary to give it with an adequate amount of added estrogen.

Amenorrhea—Secondary amenorrheas of functional origin which are

of less than six months' duration will almost invariably respond with bleeding within three days after the administration of 40 to 60 mg of progesterone if injected over a period of two to five days (Zondek¹⁵). Usually we give the hormone in three equal daily injections. Some patients with amenorrhea up to two years of duration may respond similarly. In amenorrheas of longer duration and also in primary amenorrheas it is usually necessary to prime the patient first by giving moderately large dosages of estrogen for one to three weeks before giving the progesterone, or the estrogen may be given simultaneously with the progesterone. As shown by Zondek,¹⁵ the use of alpha-estradiol 0.5 to 1.0 mg given together in the same syringe with progesterone 10 mg daily for five days works very well in these cases.

For oral therapy diethylstilbestrol 0.5 to 1.0 mg may be given daily for five days to two weeks followed by anhydro-hydroxy-progesterone (pregneninolone) 60 to 80 mg daily for five days. The results are sometimes not quite as good as by injection.

Large dose progesterone, or progesterone and estrogen treatment has in our experience resulted in bleeding in patients with either primary ovarian or gonadotropic deficiencies. After inducing this type of bleeding for three consecutive months a considerable proportion of the patients will have one to three spontaneous "periods." A small proportion will continue to menstruate regularly for a longer period of time during which pregnancy may occur.

Functional Bleeding—Intermenstrual bleeding occurring in anovulatory cycles will usually respond to the administration of moderate dosages of estrogen and progesterone given from the tenth to the twenty-fifth days of the cycle. However, equally good results are usually obtained with estrogens alone. In menorrhagia associated with a hyperplastic endometrium (so-called "hyper-hormonal" bleeding), especially if the cycle has been delayed, the administration of progesterone 5 mg twice a week during the last two weeks may be helpful. In other types of functional bleeding the use of progesterone is not of consistent help.

Early Miscarriage—Some patients are believed to abort because of the failure of the corpus luteum. Where this is suspected we have found it helpful to start such patients on full substitution therapy as soon as pregnancy is suspected. We give progesterone 10 mg three times weekly with estradiol 10,000 rat units at the same time or diethylstilbestrol 1 to 2 mg orally daily. This treatment is continued until the sixteenth week of gestation and is then gradually withdrawn. In many instances we gradually increase the stilbestrol to 5 mg daily. We have never experienced any untoward results from this type of

treatment and have been able to carry to term a number of habitual aborters, some of whom miscarried previously on progesterone alone (without estrogen) Karnaky¹⁶ has reported good results with estrogen alone.

Dysmenorrhea—Progesterone is commonly given a therapeutic trial in patients with dysmenorrhea on the assumption that as a uterine "sedative" it will lessen uterine cramps. The results in such cases are usually quite disappointing and not infrequently the dysmenorrhea is made more intense. This is not surprising when we recall that the majority of patients with dysmenorrhea have normal ovulatory cycles and therefore do not have a corpus luteum deficiency, furthermore the inhibition of the corpus luteum phase by the administration of large dosages of estrogens early in the cycle not infrequently results in a painless period. Until more is known concerning the factors underlying dysmenorrhea, it is doubtful that endocrine therapy will be wholly successful.

ANDROGENS (TESTOSTERONE)

General Indications—Although the female adult excretes almost as much androgenic hormones as the male the sources, i. e., the precursors of these in the female are imperfectly known, and concerning their influence on normal menstrual physiology we can at present only conjecture. Despite this the male sex hormone, testosterone, has proved to be a potent gynecologic weapon, and it would indeed be of inestimable value if it were not for the undesirable masculinizing effects which limit its use. Testosterone has an "anti-estrogen" effect by virtue of the fact that it tends to neutralize or overcome some of the effects of estrogens on the end organs including the endometrium, myometrium, vaginal and cervical epithelium and breasts, and also because it inhibits the gonadotropic function of the pituitary. Testosterone is also believed by some to have a direct effect on the blood vessels of endometrium, and by others to exert a progesterone-like effect on the myometrium. Whether testosterone exerts any direct effect upon the ovary is a moot point.

The masculinizing effects of testosterone generally appear in the following sequence, oiliness of the skin and scalp, acne, hirsutism of face, then of chest, then of abdomen and limbs, deepening of the voice, and enlargement of the clitoris. The oiliness of the skin and acne generally disappear soon after the medication is stopped. Hirsutism may slowly regress but not uncommonly persists and rarely continues to become worse after the hormone is withdrawn. Deepening of the voice regresses only very slowly and singers generally

complain that the original pitch does not return, enlargement of the clitoris, if it occurs, is particularly likely to persist

In the treatment of gynecologic disorders^{17, 18, 19} testosterone is most commonly used for its inhibiting effect on the endometrium in the treatment of various types of functional bleeding, and more recently in the treatment of endometriosis²⁰ Like the estrogens it can be used to inhibit the pituitary for the treatment of the menopausal syndrome in those cases in which estrogens are contraindicated, although the clinical results are not nearly so effective It may also be used to inhibit lactation in the puerperium, exerting its influence both on the pituitary and the breasts

Functional Bleeding—Testosterone may be used as a palliative measure in all types of functional bleeding, but since its effect is to produce an atrophic endometrium it is apparent that it is often not the most physiologic choice and has the added disadvantage of undesirable side effects In *functional* bleeding at the menopause (as proved by diagnostic curettage) androgens may be particularly indicated because fertility is no longer desired Testosterone propionate can be given by injection in dosages of 25 mg two or three times weekly until the bleeding stops, after which the dosage may be cut to 10 mg twice a week until there is no tendency for recurrence of bleeding Methyl testosterone may be given orally, but five times the dosage is required It is particularly useful for "maintenance" therapy in dosage of 5 to 10 mg daily until it can entirely be withdrawn In order to avoid hirsutism it is generally agreed that the dosage should be kept under 300 mg of testosterone propionate per month (25 mg three times weekly) A much safer rule is to begin cutting the dosage as soon as acne appears, regardless of the amount being given, since some women are particularly sensitive to the masculinizing effect If this type of bleeding is not promptly and effectively controlled by small or moderate dosages of testosterone, the use of radium or surgery if indicated is generally preferred

Most cases of severe pubertal bleeding respond better to androgen therapy than to other types of endocrine treatment. This syndrome is generally characterized by high gonadotropin and low or moderate estrogen values, the endometrium may be hyperplastic or atrophic The administration of estrogens or progesterone is sometimes beneficial but not infrequently they precipitate further bleeding During the first week of treatment as much as 150 mg of testosterone may be required to control the bleeding, thereafter the dosage can be reduced For the first several months it is usually necessary to continue with 30 to 50 mg a week, then 10 mg of methyl testosterone daily

by mouth during the last two weeks of each cycle including the bleeding phase, and then 10 mg only during the period of flow, until finally the hormone can be entirely withdrawn. If an excess of testosterone is given it is not uncommon for the period to be delayed as much as a month or more.

Dysmenorrhea.—Testosterone is believed by some to have a relaxing effect on the myometrium and has therefore been employed for the treatment of dysmenorrhea. We have obtained favorable results in only a moderate proportion of patients thus treated. The dosage suggested is 10 to 25 mg of testosterone propionate twice a week during the last two weeks of the cycle or 5 to 10 mg of methyl testosterone orally from the fifteenth to the twenty-fifth days of the cycle. Such therapy should not be used indefinitely because of possible accumulative arrhenomimetic effects.

SYMPOSIUM ON NEW DEVELOPMENTS IN MEDICINE

THE MODERN TREATMENT OF CIRRHOSIS OF THE LIVER

W HALSEY BARKER, M.D *

PRIOR to the last decade the treatment of cirrhosis of the liver was largely symptomatic. A high carbohydrate diet was sometimes utilized on the grounds that carbohydrates exerted a sparing action upon the liver. Since alcohol was thought to be an important etiologic factor, the victim of cirrhosis was urged to become a total abstainer. Diuretics and paracentesis were employed as indicated for relief of ascites, and at times the surgeon was called upon to perform an omentopexy. However, none of these measures was of more than temporary value, and the prognosis in cirrhosis, once ascites had developed, continued to be practically hopeless. Indeed, it was in the rarest of cases that ascites ever cleared up. Ratnoff and Patek¹ present an excellent discussion of the natural history of Laennec's cirrhosis of the liver in their analysis of 386 cases.

ETIOLOGY OF CIRRHOSIS

The etiology of cirrhosis of the liver remains far from settled. In searching for factors that predispose to cirrhosis and thus may bear upon its etiology, Patek² found one glaringly prominent fact, namely, that *alcoholism* is the most common antecedent factor in this disease in the Western Hemisphere. Yet in about 30 per cent of cases seen at autopsy, there had been no story of alcoholism. Furthermore, when he examined the data on chronic alcoholism, he found that only a small proportion of the victims, variously estimated at from 1 to 25

From the Department of Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland.

* Associate in Medicine, Johns Hopkins University School of Medicine, and Physician in-charge, Clinic for Gastro-Enterology and Nutritional Diseases, Johns Hopkins Hospital.

per cent, develop Laennec's cirrhosis. It seemed probable that the association was intimate but not direct, that alcoholism per se did not cause cirrhosis of the liver. The fact that the disease occurs commonly in India, Java and Ceylon, where alcoholism is rare, would support this interpretation. Moreover, there would seem to be incontrovertible evidence that cirrhosis may follow severe toxic hepatitis (e.g., from carbon tetrachloride or arsenical drugs) and so-called infective or epidemic hepatitis in nonalcoholic individuals.

Since alcoholic beriberi and pellagra had been shown to be similar to the endemic forms of these diseases, it seemed plausible to Patek that the correlation between alcoholism and cirrhosis of the liver might also be due to a coexisting *nutritional deficiency*. This hypothesis appeared particularly attractive in view of the high incidence of vitamin B-complex deficiency noted in patients with cirrhosis, as, for example, Wayburn and Guerard's³ report of multiple peripheral neuropathy in 17 per cent of a large series of cirrhotic patients. The trouble with the severe alcoholic is that he forgets to eat, thus it seems fair to assume that many of the various morbid states to which an alcoholic is subject are primarily manifestations of vitamin deficiency. Although alcohol conceivably may exert toxic effects in the face of a poor diet, it must play a minor role at best, since all of the deficiency syndromes may develop in total abstainers on deficient diets.

An abundance of experimental evidence has accumulated attesting to the etiologic role of nutritional deficiency in the production of liver disease. In 1924, Allan and his associates⁴ reported that depancreatized dogs receiving adequate amounts of insulin and a diet of lean meat, sucrose and bone ash did not survive for longer than a few months. They also observed that failure of liver function due to fat infiltration of the liver found in such animals could be prevented by adding raw pancreas to the diet. These observations provided the necessary stimulus for a tremendous amount of research on lipotropic substances,⁵ or substances preventing fat deposition in the liver, among them lecithin, "lipocair," choline and inositol. MacLean and Best⁶ in 1934 reported that fat was deposited in the liver of rats kept on a high-fat intake and this fatty deposition could be prevented by giving sufficient choline (now generally regarded as a member of the vitamin B complex). Subsequently, Gyorgy and Goldblatt⁷ produced fatty livers with necrosis in rats maintained on a diet deficient in the vitamin B complex even though supplemented with thiamine, riboflavin and pyridoxine. The addition to the diet of yeast, a yeast extract, or 2 mg of choline a day usually prevented the changes in the liver. Rich and Hamilton⁸ succeeded in reproducing true cirrhosis of the liver in rabbits fed a deficient diet. The development of this experimental cirrhosis was not prevented by the addition of thiamine, riboflavin, pyridoxine, nicotinic acid or vitamins A, D and E to the basal diet,

whereas a daily supplement of 5 gm. of dry brewer's yeast gave full protection Rhoads and Miller⁹ observed that the ability of the liver to excrete intravenously injected bilirubin was reduced in dogs when the animals were fed a diet lacking in the vitamin B₂ complex and that this function could be restored by the feeding of a normal diet or by the administration of crude liver extract Many other studies indicate a protective action against hepatotoxins by the feeding of yeast, choline, methionine or high protein diets

Interpretation of disease in man in the light of experimental work in animals must be made with the utmost caution However, certain clinical observations already mentioned suggest that *vitamin deficiency* may be an all-important etiologic factor in fatty liver and cirrhosis of the liver in human beings Undoubtedly, clinical and experimental observations were of equal importance in giving impetus to the development of the modern treatment of cirrhosis by a nutritious diet high in calories, protein and vitamins Before taking up the details of this dietary treatment of cirrhosis, it might be well to review briefly the symptomatology of the disease and the factors affecting the prognosis

SYMPTOMATOLOGY AND PHYSICAL SIGNS

The most important symptoms of cirrhosis in Patek's large series were, in order of frequency, as follows abdominal swelling, peripheral edema, weight loss, nausea and vomiting, abdominal pain, and hematemesis The most common *initial* symptoms and signs occurred in the following order swollen abdomen, abdominal pain, hematemesis, edema of legs, jaundice, nausea and vomiting and weakness Physical signs in the series of 386 patients were listed thus ascites 78 per cent, palpable liver 75 per cent, jaundice 65 per cent, edema 61 per cent, palpable spleen 44 per cent, hemorrhoids 27 per cent, fever 24 per cent, collateral venous circulation 23 per cent, vascular spiders 15 per cent, and a number of other less specific manifestations, among them hemorrhagic phenomena.

CLINICAL COURSE AND PROGNOSIS

Ratnoff and Patek succeeded in following 245 of their series of 386 patients until their death, more than 60 per cent of these deaths occurred within one year of the first symptoms of the disease. An additional 117 patients were lost to follow-up, leaving only twenty-four patients known to be alive at the time the records were reviewed Spontaneous loss of ascites occurred in only about 7 per cent of the cases After the onset of ascites 47 per cent of the patients survived six months, 32 per cent one year, and but 17 per cent survived two years Following the onset of jaundice (superimposed upon pre-existing cirrhosis) the survivorship curve was very similar to that following the onset of ascites Of the 106 patients in the series who

suffered from hematemesis, 40 per cent died within one month of the initial hematemesis, with an additional 30 per cent succumbing by the end of the first year. However, if a patient survived one year following hematemesis, he had a good chance of surviving several years longer.

The most common causes of death in cirrhosis, according to these same authors, are *liver failure* or *cholema*, an ill-defined state in which the patient may become stuporous or delirious, finally sinking into coma (jaundice is usually but not invariably present), *hematemesis* from ruptured esophageal or gastric varices, and *secondary infections*.

The prognosis following omentopexy, should the patient survive the initial postoperative period, was at first considered to be better than without treatment. Recent studies, however, indicate that although improvement may be noted in individual instances, the average prognosis for patients with cirrhosis is not appreciably changed by operative therapy. There were thirty-four postoperative deaths in Ratnoff and Patek's series, representing an operative mortality of 40 per cent.

DIETARY TREATMENT OF CIRRHOSIS

In 1937 Patek¹⁰ published a preliminary report on the treatment of alcoholic cirrhosis with a nutritious diet together with vitamin supplements. Convinced that the improvement that followed treatment appeared to be outside chance expectations, he was encouraged to extend the program of treatment to embrace a larger series of patients over a longer period of time and he recognized the importance of comparing the course of patients so treated with that of a similar group of hospitalized patients who had not received special dietary therapy. This led to the review of the 386 "untreated" cases by Ratnoff and Patek,¹ the 1941 report by Patek and Post¹¹ on fifty-four patients with decompensated cirrhosis treated with the new dietary regimen, and the 1943 paper by Patek² furnishing a more recent follow-up on the 1941 series.

Through a careful analysis of the symptomatology and physical signs in his group of fifty-four "treated" patients and a comparison of the figures thereby obtained with those for the "untreated" group of 386 patients, Patek was able to present convincing evidence that the "treated" group prior to receiving treatment was, if anything, more severely afflicted than the "untreated" group. Eighty-nine per cent of the "treated" patients had ascites when first observed, while 63 per cent had jaundice and 24 per cent gave a history of hematemesis. In other words, it is fair to conclude that the "treated" and control series are entirely comparable as far as severity of the liver condition is concerned. And as a corollary to this conclusion, it would seem justifiable to accept any statistically supported improvement in the average survival period for the treated group as distinctly significant.

What then is this *Patek dietary regimen*? The diet is rich in protein and ample in carbohydrate and fat. Containing approximately 3600

calories, it is distributed in the following proportions protein 139 gm (including the protein in the brewer's yeast), fat 175 gm., and carbohydrate 365 gm. The diet* consists largely of meat, milk, eggs, fruit and green vegetables. Meat is served twice daily, milk five times daily—three times with meals and twice with 25 gm of powdered brewer's yeast. The yeast is fed in graded, increasing doses up to the final amount. Even so, certain patients cannot tolerate brewer's yeast, for these, oral vitamin B complex has been substituted in the form of liquid yeast concentrates. In addition, thiamine hydrochloride (5 mg) is injected intramuscularly every day, and concentrated liver extract (5 cc) twice weekly. During the critical period of hepatic decompensation the cirrhotic patient, to whom food is often loathsome, presents a real challenge to nursing and dietetic care. Patek urges that the intake at each meal be charted in order to keep account of the actual consumption. In patients with ascites salt intake is restricted only by the exclusion of a salt shaker from the tray, fluids are allowed up to 2000 cc. daily. Too rigid restriction of salt and water may prove harmful to these patients by precipitating symptoms of hypochloremia and dehydration. It should be pointed out that, with each abdominal tap, considerable salt is removed as well as an appreciable quantity of protein. Nonetheless, it is desirable to tap abdominal fluid before the patient is too distended, for this interferes seriously with the appetite. In an attempt to space out the intervals between paracenteses, mercurial diuretics may be injected once or twice a week following the oral administration of 3 to 4 gm of ammonium chloride daily for several days.

Of Patek's fifty-four patients treated on this regimen, twenty-two showed signs of progressive failure and went on to die, eighteen of them succumbing within the first five months of starting treatment. Twelve of the fifty-four patients were partially improved as shown by the loss of ascites and improvement in liver function tests, five were lost sight of, three remained free of ascites but failed to regain robust health, while four subsequently died after being ascites-free for over two years in each instance. The remaining twenty of the fifty-four patients were regarded as showing signs of "clinical recovery," their improvement fulfilling three criteria: (1) gain in weight and strength permitting the patient to resume his previous activity, (2) loss of ascites, edema and jaundice without recurrence, (3) changes in serum proteins, Takata-Ara and bromsulfalein excretion tests *towards* normal values. In the latter group although it seemed highly unlikely that the histologic changes were completely reversed it was clear that the process had been arrested or partially reversed.

Comparing the control and "treated" series Patek and his associates showed that 60 per cent of the treated patients, in contrast to only about 7 per cent of the control group, experienced the spontaneous

Complete dietary list may be found in the article by Patek and Post.¹¹

disappearance of ascites The period of survival of patients after the onset of ascites showed the following differences

	Control	Treated
At 6 months	57%	72%
At 1 year	37%	57%
At 2 years	22%	45%

These figures have been subjected to statistical analysis and their significance has been established beyond the shadow of a doubt Patek predicts that far superior results might be expected if the dietary treatment could be instituted earlier in the disease before signs of hepatic decompensation had appeared

His interest stimulated by Patek's original report on the dietary treatment of cirrhosis and the volume of suggestive experimental work already mentioned, Snell¹² began treating cirrhotic patients with a nutritious diet supplemented with various vitamins His regimen differed materially from that recommended by Patek The diet was high in carbohydrate (500 gm), low in fat (about 60 gm), and rich in proteins not derived from meat sources (110 gm), providing roughly 3000 calories per day The protein component of the diet was derived chiefly from vegetables, milk and egg-white, meat being kept at a minimum The basis for this change in protein composition was Bollman's report that animals with experimentally produced hepatic injury are made worse by the administration of meat or meat extracts while tolerating protein from other sources without harmful effect Snell supplemented his diet with various pure vitamins, crude oral liver extract, and yeast or yeast concentrates In order to facilitate absorption of fat-soluble vitamins, patients were given animal bile salts, 0.3 to 1.0 gm with each meal This program gave very encouraging results in a group of fifty decompensated cirrhotic patients so treated A few remarkable "cures" with disappearance of ascites were encountered, one of the most striking in a man aged 72 who after two years of almost weekly paracentesis remained free of ascites and in good health for one year The results of treatment were regarded as "excellent" in 44 per cent of the entire group,¹³ although only 22 per cent were entirely free from ascites at the time of the report Snell agrees with Patek that an even higher incidence of "cures" is to be expected among patients who present various degrees of fatty metamorphosis, degeneration and necrosis without extensive periportal fibrosis and great restriction of portal blood flow

In a recent report on the diagnosis and clinical course of fatty liver in seventy alcoholic patients, Keefer and Fries¹⁴ stress the therapeutic value of a high-carbohydrate, low-fat diet with a moderate amount of protein, supplemented with vitamin preparations and liver extract. They regard the fatty liver as the precursor of cirrhosis, but point out that ascites, jaundice, and death may occur during the stage when the

liver is filled with fat and before actual fibrosis has developed. In some cases, the process appeared to be reversible. The recognition of this disorder in its early stages and the use of appropriate treatment was followed in many instances by recovery.

For the past several years we have been keenly interested in the dietary treatment of cirrhosis at the Johns Hopkins Hospital. To date too few patients have been so treated to justify any final conclusions, but we have seen sufficiently encouraging results to warrant a continuation of the regimen. In general, it has been our policy to adhere fairly closely to the Patek diet with the exception that the fat content of the diet has been considerably reduced for patients with jaundice or diarrhea. Since Snell's reasons for withholding meat are based on purely experimental grounds not necessarily applicable to the human liver and since meat is known to contain protein of "highest biologic value," we have not eliminated meat from our diet, but rather supplied it in liberal portions with complete impunity as far as we could ascertain. We have supplemented the diet with 30 to 50 gm of brewer's yeast powder a day and polyvitamin capsules in numbers sufficient to supply at least twice the estimated normal adult requirement for the vitamins of proven importance in human nutrition, namely vitamins A, C, D, thiamine, nicotinic acid (or the amide), and riboflavin. Where hemorrhagic phenomena were observed with prolongation of the prothrombin time, vitamin K was administered either parenterally or orally along with bile salts to promote its absorption. Intramuscular injections of crude (rather than concentrated) liver extract have been given in some cases, especially when macrocytic anemia was present. Furthermore, the oral administration of crude liver extract powder has been employed in certain instances. In view of the experimental work on the lipotropic action and protective effects exerted by choline on the liver, it seemed plausible to Wintrobe and the writer to administer this substance to patients with cirrhosis as an additional supplement to the measures already outlined. At least ten patients have now received choline chloride, 15 gm a day, administered in the form of a 10 per cent elixir prepared by the hospital pharmacy, in doses of 5 cc after each meal. No untoward effects have been noted after the continued administration of choline for weeks or even months. It is as yet too early to speculate upon the possible merits of choline therapy in cirrhosis.

ADJUNCTIVE THERAPEUTIC MEASURES

Combating Secondary Vitamin Deficiency—In addition to the highly suggestive evidence already presented that vitamin deficiency plays an important role in the etiology of liver disease, it has been firmly established that preexisting liver disease predisposes toward the development of numerous and varied manifestations of vitamin deficiency. Liver disease may contribute to the deficiency of the fat-soluble vitamins

A and K in one of three ways (1) failure of proper absorption in patients with jaundice, (2) failure of storage of the vitamins in the diseased liver, (3) disturbance of intermediary metabolism of the vitamins in the damaged liver. In patients with obstructive jaundice or hepatitis the dearth of bile salts in the intestinal tract results in poor absorption of fats and fat-soluble vitamins. Carotene furnishes the chief source of vitamin A in the average diet, and the normal liver converts carotene to vitamin A through the action of an enzyme, carotenase. Since a severely damaged liver will not effect this conversion, it is not surprising that low blood levels of vitamin A along with clinical manifestations of vitamin A deficiency (e.g., night blindness, keratomalacia, and epithelial metaplasia of various organs) have repeatedly been described in patients with cirrhosis or other forms of liver disease. Therapy or prophylaxis should consist in large doses of vitamin A administered orally with bile salts or large parenteral injections of vitamin A. Little improvement is to be expected from a high carotene intake in patients with severe liver damage.

The recognition of the etiologic role of vitamin K deficiency in the hemorrhagic diathesis so common in patients with jaundice or severe liver damage represents one of the most important contributions to medical knowledge within the last decade. This hemorrhagic tendency has been conclusively shown to be due to lowered plasma prothrombin, which in turn results from inadequate absorption of vitamin K, failure of the severely damaged liver to utilize vitamin K in the formation of prothrombin, or a combination of these two conditions. The failure of jaundiced patients to absorb vitamin K may be controlled by the oral administration of the bile salts along with vitamin K preparations or the parenteral administration of a purified vitamin K derivative such as 2-methyl-1, 4-naphthoquinone (1 to 4 mg. a day intramuscularly). If the liver is so severely damaged that it cannot produce prothrombin in spite of an adequate supply of vitamin K, bleeding will not be influenced by either of these methods of administering vitamin K and the prognosis becomes extremely grave. Under such circumstances, transfusions of freshly drawn blood should be given to supply prothrombin directly. The full understanding and proper application of these principles by surgeons and internists alike will go far toward decreasing risk from hemorrhage in jaundiced patients.

In addition to the special function of the liver with reference to vitamin A and K, the liver is known to serve as a storage depot for the majority of vitamins (A, B-complex, C, D, K) and probably provitamins as well. Hence, patients with severe liver disease are bound to have inadequate reserves and are, therefore, more likely to develop outspoken manifestations of vitamin deficiency under the added strain of any severe infection or curtailment of food. This situation affords still another reason for our advocating the liberal use of pure vitamins.

in addition to the high-vitamin diet and crude vitamin sources in the treatment of cirrhosis

Treatment of the Anemia—Macrocytic anemia with leukopenia is not an uncommon finding in patients with cirrhosis, even though their gastric juice may contain free hydrochloric acid and Castle's intrinsic factor. It has been postulated that this macrocytic anemia is due either to failure of the diseased liver to store adequate reserves of the anti-pernicious anemia principle or to improper metabolism of this principle in the diseased liver. This macrocytic anemia will respond to oral or parenteral therapy with liver extract in certain instances, but the response is rarely so dramatic or so complete as in patients with true pernicious anemia, and the macrocytic anemia of certain cirrhotics appears to be unaffected by liver therapy.

If there has been repeated blood loss from esophageal varices or constant oozing from hemorrhoids, the anemia in cirrhosis may be hypochromic and microcytic. In such cases iron therapy is indicated and best administered in the form of ferrous sulfate 0.2 to 0.4 gm after each meal. Transfusions, of course, become necessary in patients suffering large or prolonged hemorrhages from ruptured varices.

Diuretics and Paracentesis.—When ascites or edema is present, the daily fluid intake should be limited to 2000 cc. and the salt intake moderately restricted to the extent of permitting no salt on the tray. Furthermore, since tense ascites interferes seriously with appetite, intestinal motility and the absorption of food, it is most important to combat this condition vigorously. It is desirable to postpone paracentesis as long as possible, hence, diuretic measures should first be given a trial. As a rule we give ammonium chloride (in the form of enteric-coated tablets) 3 to 4 gm a day by mouth for several days, followed by one or more intravenous injections of mercupurin, 1 to 2 cc. at a time for one day to three days in a row. This procedure may be safely repeated at seven to ten day intervals. When diuretic measures fail to accomplish adequate relief from ascites, then paracentesis becomes imperative. The intervals between paracentesis can best be gauged by the weight curve, the condition of the abdomen, and the subjective status of the patient. There is no point in encouraging stoicism on this score.

Surgical Treatment of Ascites and Varices.—For many years the Talma operation or *omentopexy* (an operation designed to bring the omentum out into the abdominal wall in the hope of facilitating the development of collateral venous circulation) was thought to be a valuable measure for the relief of ascites. However, the operative mortality was high since cirrhotics tolerate anesthesia and surgical procedures poorly and the end results in those who survived were rarely good enough to arouse enthusiasm for this form of therapy. In recent years omentopexy has been largely discarded as a relatively useless therapeutic measure.

More recently *injection of a sclerosing agent* into esophageal varices

through an esophagoscope has been tried in an attempt to thrombose these veins and thereby prevent future hemorrhages. This procedure is a relatively new one and must await the test of time in a larger series of cases before its true value can be assessed. *Ligation of the coronary vein* of the stomach has been carried out in the hope of taking part of the load off of the esophageal varices. *Operative anastomosis of the splenic vein to the renal vein* has also been suggested as a means of shunting a considerable volume of blood away from the portal system, this is, of course, a modified Eck fistula.

The most radical surgical procedure designed to relieve ascites and to decrease the strain upon esophageal varices is *splenectomy*. From the hypothetical standpoint it would be desirable to remove the spleen in all cirrhotic patients with ascites or varices in order to reduce by no inconsiderable quantity the amount of blood entering the portal system. Unfortunately, the majority of patients with cirrhosis tolerate poorly prolonged anesthesia and the shock of such a major operative procedure. However, in selected cases splenectomy may be followed by striking improvement as illustrated in one of the cases to be reported briefly.

CASE REPORTS

In order to illustrate some of the therapeutic principles that have been described, we should like to present brief abstracts of four case records of patients treated by the writer within the last three years.

CASE I—J H., a white liquor salesman, aged 34, was first seen in February 1942 complaining of jaundice and abdominal swelling. His father, a heavy drinker, had died of cirrhosis of the liver in his 40's. Although always a nervous, high-strung person, the patient had enjoyed excellent health up until the winter of 1939 when he suffered a severe nervous shock as the aftermath of seeing his son struck by a truck. He lost his appetite, ate little, and slept poorly for the next eighteen months. During this period he took fruit juices, fruit, milk, bread and butter, but no vegetables, meat or eggs. He drank from 4 ounces to a pint of whiskey a day. He lost 30 pounds in weight and became so weak he was obliged to go to bed whence he was admitted to a hospital delirious with generalized edema and albuminuria. He was eventually discharged with a diagnosis of liver and kidney trouble. He returned to work very weak, but was eating better, including meat in his diet twice a week and three polyvitamin tablets daily. He claimed he took no more alcohol except two to five bottles of beer a day. In August 1941 he began to feel sluggish, lost his appetite, ate poorly once more, chiefly liquids, and again lost weight. In December, jaundice set in and progressively deepened with frequent light pasty stools and dark urine. There had been fluctuating swelling of the abdomen and legs during the six months prior to admission. There was no gross hemorrhage from the gastrointestinal tract, but some blood-streaking on the stools from straining.

The principal *physical findings* were deep jaundice, edema of the legs, numerous "spider" angiomas over the neck and shoulders, dental caries, lungs clear, heart pushed upwards and outwards, sounds clear except for systolic murmur at the apex, pulse regular, blood pressure 145/85, well marked ascites with evidence of collateral venous circulation over both flanks, liver tremendous with upper border of dullness at right fifth rib and lower edge felt 2 cm. below level of umbilicus on the right. The edge extended across the epigastrium just above

TABLE 1 —LABORATORY FINDINGS IN CASE 1

* Results of prothrombin time expressed as 62/20 means for patient 62 seconds as compared with normal control 20 seconds.

† At this time the serum sodium was distinctly low, 129.0 milliequivalents per liter

the umbilicus to disappear beneath the left costal margin. The liver felt hard but smooth except for a notch between the lobes in the epigastrium. The spleen was not felt. There were no external hemorrhoids. Neurologic examination was normal.

The admission diagnosis was cirrhosis of the liver with a superimposed episode of acute hepatitis or hepatic necrosis. Neoplasm of the liver was considered possible but unlikely.

Laboratory Findings The blood count on admission showed no anemia but a marked polymorphonuclear leukocytosis: red blood cells 4,870,000, hemoglobin 14.5 gm or 100 per cent, volume packed red blood cells 42.2, giving normal indices, leukocytes 17,200 with juveniles 11 per cent, segmented neutrophils 81

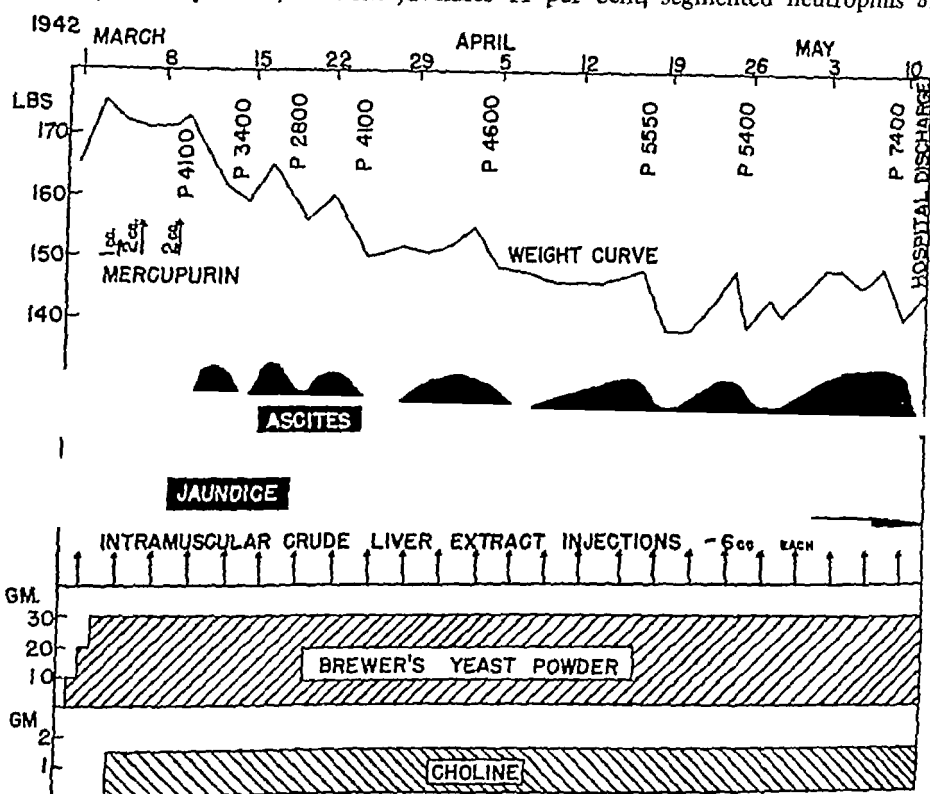

Fig 45 (Case I, J H) —Chart shows weight curve, fluctuating ascites, disappearance of jaundice, and various therapeutic measures employed over the 11-week period of hospitalization "P" equals paracentesis, the volume of ascitic fluid in cubic centimeters removed is designated for each paracentesis

per cent, lymphocytes 5 per cent, monocytes 3 per cent, sedimentation rate (Wintrobe method) markedly accelerated, 44 mm corrected to 36 mm. Urine was slightly cloudy, dark brown, specific gravity 1.010 acid, albumin 2 plus, bile 4 plus, urobilinogen negative, microscopic examination showed bile-stained hyaline and granular casts, but no erythrocytes, leukocytes or amino acid crystals. Serologic test for syphilis was negative. Stool was pasty gray, negative for occult blood and bile pigment. The remainder of the laboratory findings during the patient's stay in the hospital are summarized in Table 1.

Clinical Course Certain of the more important clinical features and therapeutic measures employed are depicted graphically in Figure 45. This patient was desperately ill on admission and seemed to grow worse during the first two

weeks with increasing jaundice, ascites which recurred rapidly after each paracentesis and failed to respond to diuretic measures, and an intractable fatty diarrhea which persisted for seven weeks, unaffected by orally administered bile salts or pancreatic enzymes. A diet high in protein, carbohydrate and vitamins but low in fat was prescribed, supplemented with brewer's yeast power 30 gm a day polyvitamin capsules* (two a day), choline chloride 1.5 gm a day and intramuscular injections of 6 cc. crude liver extract every third day. Since the patient was too ill to consume his full diet, additional carbohydrate was supplied in the form of 10 per cent glucose intravenously almost every day for the first four weeks. He ran an irregular fever as high as 102° F at times. As a result of too rigid salt restriction and loss of sodium chloride at paracentesis, he became dehydrated with hypochloremia, prerenal azotemia and moderate acidosis. When the salt intake was increased the nonprotein nitrogen fell to normal as the blood chloride rose to a normal level. However, at this stage the acidosis was still pronounced as shown by the persistent reduction in the carbon dioxide combining power. Dr. George Thorn interpreted this acidosis as resulting from bicarbonate loss in which the prerenal azotemia and the strongly acid ash (high protein) diet were the chief contributory factors. The low serum sodium at a time when the serum chloride had returned to normal fits in with Dr. Thorn's interpretation. The patient became delirious and was extremely difficult to manage during the azotemic acidotic phase of his illness. The marked leukocytosis was thought to be due to extensive hepatic necrosis. In view of the much prolonged prothrombin time on admission, the patient was given synthetic vitamin K 2 mg intramuscularly daily for the first three weeks, 1 mg every second day thereafter. The fact that the prothrombin time improved under vitamin K therapy was one of the few encouraging signs during the early weeks of treatment.

Throughout the first three weeks little hope was held out for the patient's recovery. Then he rather suddenly began to improve as shown by increase in appetite, cessation of loss of flesh weight, return of mental faculties, diminution in size of the liver, decrease in jaundice with eventual return of serum bilirubin to normal, and gradual decline of white blood cells to normal. He was discharged from the hospital on May 12, ten weeks after admission on the full dietary regimen, and required no further paracentesis although it was necessary to administer intravenous mercupurin on May 22 and June 1 to combat recurrent ascites. He experienced an excellent diuresis on each occasion, and thereafter the ascites slowly subsided spontaneously.

When the patient was last seen on June 18 there was practically no ascites, the liver was only 3 cm. below the right costal margin, and the tip of the spleen was felt for the first time. He was feeling fine and had regained flesh. Shortly thereafter he returned to work. Repeated efforts to persuade the patient to report at regular intervals were unsuccessful. It was learned from his wife that after remaining abstemious and following his therapeutic regimen for several months, during which period he seemed perfectly well, he began drinking once more, stopped eating and eventually died in August 1943 with jaundice and ascites.

Comment—A 34 year old alcoholic liquor salesman was admitted to the hospital desperately ill with what was regarded as acute hepatic necrosis, presumably superimposed on underlying cirrhosis. His illness was characterized by fever, leukocytosis, deep jaundice, ascites

* The polyvitamin capsule used in treatment of this patient and the other three patients was Dayamin (Abbott). Each capsule contained vitamin A, 10,000 U.S.P. units; vitamin D, 1000 U.S.P. units; thiamine hydrochloride, 3 mg; riboflavin, 2 mg; ascorbic acid, 50 mg; nicotinamide, 20 mg.; pyridoxine hydrochloride, 1 mg; pantothenic acid, 1 mg.

and fatty diarrhea. On a modified Patek regimen, including the oral administration of choline chloride and intramuscular crude liver extract, he made a remarkable recovery with complete clearing of jaundice and ascites, only to succumb fifteen months later after returning to his alcoholic ways and abandoning his therapeutic regimen. This type of patient should have excellent prospects of a permanent "cure" provided he could be maintained indefinitely on a nonalcoholic regimen with a nutritious diet.

CASE II—P. B., a white retired businessman and farmer, aged 66 years, was admitted to the hospital on March 10, 1944 complaining of jaundice, abdominal swelling and loss of appetite. His father had died of cancer of the throat. The patient had enjoyed excellent general health throughout his life up to the onset of the present illness. For ten years he had noted a postnasal drip and nasal obstruction, attributed to sinusitis. He had also suffered from arthritis of his shoulders and back for at least ten years. For many years he had been a heavy drinker with the exception of one period of seven to eight years when he stopped drinking entirely. Throughout the ten years prior to the onset of the present illness he had consumed at least 1 quart of distilled spirits a week. He claimed to have eaten fairly well over this period. During the summer of 1943 the patient began to suffer from postprandial epigastric pain, he lost his appetite and was afraid to eat, although he remained partial to small servings of rare red meat. His total daily food intake was very poor and he lost a great deal of weight. Six weeks before admission he developed jaundice with generalized pruritus. This was followed by marked swelling of the abdomen and legs. There had been no hemorrhagic phenomena.

On *physical examination* the patient was an unusually tall, large framed man who seemed somewhat confused mentally. He showed evidence of weight loss over the upper half of the body, with pronounced soft pitting edema over the legs, abdomen and lower back. The complexion was bronzed with slight icterus, no vascular "spiders" were seen. The tongue was normal, lungs were clear with definite emphysema, the heart was not enlarged, sounds distant with a soft systolic blow all over, pulse regular, moderate arteriosclerosis, blood pressure 155/80. The abdomen was hugely distended with bulging in the epigastrium and both flanks, marked shifting dullness and suggestive fluid wave. The liver and spleen were not felt, there were no hemorrhoids. The neurologic examination was negative except for absent ankle jerks and questionably diminished vibratory sense in the legs.

The *admission diagnosis* was cirrhosis of the liver with ascites and mild jaundice, probably on a dietary deficiency basis in a man with a background of over-indulgence in alcohol. Carcinoma of the tail of the pancreas was considered possible but less likely.

Laboratory Findings. Blood count: red blood cells 4,320,000, hemoglobin 13.8 gm or 95 per cent, volume packed red blood cells 39.6 giving normal indices (the blood remained normocytic and normochromic throughout), leukocytes 8300 with polymorphonuclear neutrophils 81 per cent, polymorphonuclear eosinophils 1 per cent, lymphocytes 8 per cent, and monocytes 10 per cent, sedimentation rate 50 mm corrected to 36 mm in one hour (Wintrobe method). Urine was orange, clear, acid, specific gravity 1.016, no sugar or albumin, faintly positive for bile, strongly positive for urobilinogen up to 1:320 dilution, occasional leukocytes, hyaline and granular casts. Serologic test for syphilis was negative. The prothrombin time was 17 seconds as compared with normal control of 16 seconds. The remainder of the more important laboratory results throughout the period of observation are summarized in Table 2.

* Normal result is 1 gm. or more excreted within one hour after intravenous injection of 1.77 gm. of sodium benzoate

Clinical Course Important features in the clinical course and therapy of this patient are charted in Figure 46. He was kept upon the full Patek diet from the start. This was supplemented daily with 30 gm of brewer's yeast powder, three polyvitamin tablets, and later 15 gm of choline chloride. In addition he was given an intramuscular injection of 2 cc of parentosol-B* daily for the first seven weeks. Two intramuscular injections of crude liver extract caused so much local discomfort that this form of therapy was abandoned. The chart demonstrates the striking diuresis obtained on each occasion from combined therapy with oral ammonium chloride (enteric-coated tablets) and intravenous mercu-

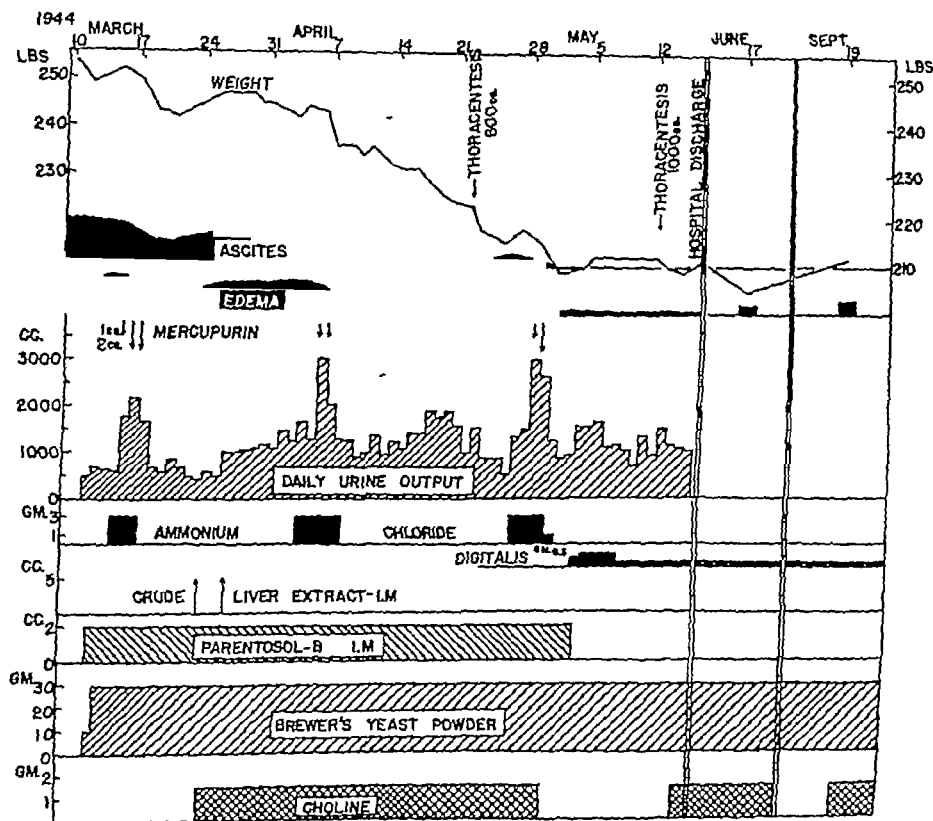

Fig 46 (Case II, P B) —Chart shows progressive loss of weight (due largely to clearing of ascites and edema), the daily urine output (with striking diuresis on each occasion that oral administration of ammonium chloride was followed by intravenous mercupurin), and various therapeutic measures employed over the 10-week period of hospitalization in March, April and May, also status of patient at subsequent periods of observation in June and September

purin, also the increasing tendency to spontaneous diuresis after the patient had been under treatment for several weeks. Since the fluid intake was kept fairly constant throughout (never over 2000 cc in one day), the fluctuation in urinary output may be regarded as significant. The loss of 40 pounds in weight shown on the chart may be attributed almost entirely to steady decrease in edema and ascites, as there was little evidence of actual loss of flesh. The ascites had dis-

* Parentosol-B (Squibb) is provided in sterile ampules for parenteral use. Each cubic centimeter contains thiamine hydrochloride 10 mg., riboflavin 4 mg., and niacinamide 200 mg.

appeared completely after seven weeks, at which time the hard liver was readily palpable 4 cm below the right costal margin and the tip of the spleen could also be felt.

After four weeks on the therapeutic regimen the patient began to exhibit evidence of steady improvement as shown by the diminishing ascites and edema the disappearance of the slight icterus with return of the serum bilirubin to normal and the decrease in bromsulfalein retention. The serum albumin remained low around 2.0 gm. per 100 cc. throughout his hospital stay. This hypalbuminemia was thought to be an important contributory factor in the edema, ascites and the right hydrothorax which developed six weeks after admission. The only peculiar features of the hydrothorax were (1) that it appeared at a time when the edema and ascites had almost cleared up and (2) that the chest fluid had an unusually high protein content (3.88 gm. per 100 cc.) and cell count (7650) for a transudate. An underlying pulmonary infarct and cardiac failure on an arteriosclerotic basis were considered as possible alternative explanations for the hydrothorax. In view of a potential element of cardiac failure, the patient was digitalized without obvious effect on the hydrothorax or the urinary output.

The patient was discharged from the hospital on May 17 in excellent condition. He was reexamined in June and September. There was no recurrence of ascites or jaundice on either occasion. Moderate edema of the legs had been present ever since he became ambulatory once more. The steady rise in serum albumin to 3.19 gm. per 100 cc. on September 20 along with the normal hippuric acid excretion test on the same date furnished convincing objective evidence of improvement in his liver function. Latest reports from the patient in November 1944 eight months after dietary treatment was inaugurated, attest to his continued good health. He has adhered strictly to the Patek diet with yeast and vitamin supplements, while taking courses of choline intermittently, ever since discharge from the hospital.

Comment—This 66 year old man with cirrhosis of the liver, quite conceivably on a dietary deficiency basis, made an excellent response to the Patek regimen supplemented with choline chloride. Since there was an excellent response to diuretic measures on three separate occasions, paracentesis was at no time necessary. The patient has remained free of jaundice and ascites for over six months, while a steady rise in serum albumin, decrease in bromsulfalein retention, and increase in hippuric acid excretion (following the injection of sodium benzoate) furnish additional objective evidence of improvement in liver function.

CASE III—E. H., a white male restaurant owner and bartender aged 56 years, was admitted to the hospital on March 3, 1943 complaining of abdominal swelling of three months duration. Family history was noncontributory. Past history revealed nothing of unusual interest except for the fact that the patient had been a heavy drinker of both beer and distilled spirits for many years. For six months prior to admission he had been eating very poorly as he put it he was "too busy to eat." He would eat chiefly potatoes and butter rarely meat, fruit or vegetables. During the six months he lost 30 pounds in weight. In December 1942, there was insidious onset of painless abdominal swelling which gradually increased. He had not noticed jaundice and had never suffered a gastrointestinal hemorrhage. There had been some swelling of the legs for several months.

The principal findings on physical examination were as follows: evidence of marked weight loss with striae on arms; slight icterus; soft pitting edema over legs and lower back with stasis eczema on lower legs; red papular eruption over

face and numerous vascular "spiders" over neck, arms and upper trunk, beefy red smooth geographical tongue, chest emphysematous, lungs clear, heart normal in size with regular rhythm and blood pressure 140/70, abdomen hugely distended with ascites, collateral venous circulation over abdominal wall. No organs or masses were felt prior to tapping the abdomen. Following paracentesis the abdomen was soft, the hard, somewhat irregular liver edge was felt just below the right costal margin and extending across epigastrium 5 cm below xiphoid. Spleen was not felt. Neurologic examination was entirely normal.

The admission diagnosis was cirrhosis of the liver with jaundice and ascites, probably on a dietary deficiency basis in a heavy alcoholic.

Important Laboratory Findings Blood count red blood cells 4,280,000, hemoglobin 13.8 gm or 95 per cent, volume packed red blood cells 39.9 giving mean corpuscular volume of 93 cu microns (a figure slightly on the macrocytic side), leukocytes 7850 with normal differential count, sedimentation rate markedly elevated to 51 mm (corrected to 37 mm.) in one hour, icterus index 18. Urine showed 1 to 2 plus albumin, urobilin but no bilirubin. Serologic test for syphilis was negative. The blood nonprotein nitrogen was 30 mg per 100 cc, fasting sugar 85 mg per 100 cc., chloride 102.6 milliequivalents per liter, total serum protein 7.50 gm per 100 cc with albumin 3.06 gm and globulin 4.44 gm per 100 cc, van den Bergh test gave a delayed biphasic reaction with serum bilirubin 1.8 mg per 100 cc. Liver function tests. Bromsulfalein test showed 30 per cent retention after thirty minutes, hippuric acid test revealed only 0.11 gm excreted at the end of one hour. Prothrombin time 24 seconds compared with normal control of 13½ seconds. Stool showed bile and gave a faintly positive test for occult blood.

Course. The patient was placed on the Patek diet (except that fat content was reduced), supplemented with brewer's yeast 45 gm, 10 per cent elixir choline 15 cc., one polyvitamin capsule, and 3 mg of vitamin K daily by mouth. Paracentesis was performed the day after admission, yielding 10,500 cc of straw-colored fluid with specific gravity 1.016, protein 10 gm per liter, 300 cells (chiefly lymphocytes). The patient remained in the hospital for eight weeks during which time he lost ground steadily, his weight falling from 175 to 137 pounds. He experienced great difficulty in taking his full diet although he made a sincere effort. Paracentesis was performed six times in all, yielding 8000 to 13,000 cc. of fluid at each tap. Ascites reaccumulated rapidly after each tap in spite of restricted intake of fluid and salt. Attempts to relieve the ascites with ammonium chloride and mercupurin met with only slight success, insufficient to forestall the necessity for repeated paracenteses. The prothrombin time failed to improve materially following the administration of vitamin K either orally or intramuscularly (this observation is of ominous import as regards the severity of the liver damage). The bromsulfalein retention was 25 per cent at the end of the hospital stay, a value almost identical with the original figure.

After discharge from the hospital the patient attempted to follow the entire regimen at home, but continued to lose weight. He required taps at weekly intervals, eventually became wildly delirious and died on July 14 following a massive hematemesis.

Comment—This case represents an instance of cirrhosis so advanced that the pathologic changes must have been completely irreversible. In spite of the dietary regimen instituted, the course was progressively downhill to death. One point of special interest was the failure of the prothrombin time to return to normal after adequate parenteral therapy with vitamin K, an indication of the severity of the parenchymal liver damage.

CASE IV—E. K., a white male electrician, aged 39 years was admitted to the hospital March 26, 1943 complaining of abdominal swelling for nearly two years. The family history was noncontributory. In the past history it was of interest that up to 1936 he had worked in a rubber heel business where he was exposed to fumes of sulfur and various solvents. There was no exposure to chemicals thereafter. Early in 1940 he suffered a severe electric shock which knocked him unconscious and caused serious burns. He spent six weeks in a hospital at the time. Appetite had been excellent with well balanced diet, and alcohol had been taken sparingly at best, not over four glasses of beer a month. In August 1941 he noticed increasing weakness, malaise and fatigue. One month later he suffered massive hematemesis two days apart, requiring admission to a hospital for transfusion. His abdomen then began to swell and exploratory laparotomy was performed with the possibility of perforated ulcer evidently in mind. A large volume of ascitic fluid was removed at operation and an omentopexy was performed. During the next four months he required paracentesis every eight to ten days, until January 1942 when a spontaneous remission in the ascites occurred and he was able to return to work. In December of that year he suddenly experienced another massive hemorrhage into the gastrointestinal tract with both hematemesis and tarry stools. Shortly thereafter abdominal swelling recurred. After several transfusions he was strong enough to go to a hospital in Philadelphia where his esophageal varices were injected in an attempt to thrombose them. Two days later he again bled profusely and there was one more hematemesis in January 1943. The patient had been treated for several months outside the hospital on the Patek regimen. In spite of this and the surgical procedures, he required four paracenteses between January and March 1943 when he was admitted to the hospital. The last paracentesis was performed ten days before, yet he was already uncomfortable from abdominal distention at the time of admission. He had lost 20 pounds during the previous six months. There had been no jaundice at any time.

On *physical examination* the important findings were as follows: moderate pallor without icterus, evidence of weight loss, soft edema about ankles, several vascular "spiders," "liver palms," tongue a beefy red but no papillary atrophy present, lungs clear, bases high, heart pushed upward, split first sound with soft systolic blow at apex, pulse regular, blood pressure 105/55, abdomen hugely distended with shifting dullness and striking fluid wave, pronounced collateral venous circulation over abdomen and lower chest, moderate-sized hemorrhoids. No organs or masses could be felt in the tensely distended abdomen before paracentesis. After tapping the abdomen was soft and relaxed; there was an upper midline scar with a large ventral hernia through which the markedly enlarged spleen protruded like an Aleutian isle rising out of the sea. The spleen was very hard, the edge fairly sharp with a distinct notch in the median border; no bruit or friction rub heard over the spleen. A hard nodular liver edge could be felt 4 cm. below the xiphoid in the epigastrium but could not be traced below the right costal margin. Neurologic examination was entirely normal.

Admission impression was Banti's syndrome (due to splenic vein thrombosis) with marked splenomegaly and secondary cirrhosis of the liver although the possibility of primary cirrhosis following exposure to toxic substances years before was considered.

Laboratory Findings: Blood count, red blood cells 3,780,000, hemoglobin 9.3 gm. or 64 per cent, volume packed red blood cells 30.3, leukocytes 3850 with normal differential formula, sedimentation rate 33.0 mm. corrected to 9.0 mm. in one hour. Urine was normal. Serologic test for syphilis was negative. Blood chemistry: nonprotein nitrogen 40 mg. per 100 cc., sugar 112 mg. per 100 cc., serum chloride 110.4 milliequivalents per liter, total serum protein 5.75 gm. with albumin 2.81 gm. and globulin 2.94 gm. per 100 cc. Prothrombin time was 20 seconds compared with control of 15 seconds. Bromsulfalein liver function test

showed 28 per cent retention after thirty minutes. The phenolsulfonphthalein kidney function test showed 95 per cent excretion in two hours, an abnormally high value as is frequently seen in liver disease.

Clinical Course The patient was placed under the Patek diet supplemented with yeast, choline and polyvitamin capsules as in the previous cases. The day after admission he vomited bloody fluid. At paracentesis 10 liters of straw-colored fluid was removed with specific gravity 1.014 and practically no cells. Six days later, 7500 cc of fluid were removed. The patient was given a transfusion and on April 6 splenectomy was performed by Dr W M Firor under sodium pentothal, nitrous oxide and local anesthesia. The liver was found to be small, hard and nodular, and about one-half normal size. The operator noted several branches of the splenic vein fully 1 cm in diameter. The left coronary vein was ligated with the splenic pedicle. The spleen weighed 840 gm. Microscopic report by Dr S S Blackman and Dr R C Clay: "The splenic tissue reveals changes which are characteristic of elevated venous tension in the splenic system. These are characterized by dilated venules and splenic sinuses which are now emptied of their blood. There is some fibrosis surrounding these sinuses and the tissues of the pulp seem quite empty. The malpighian bodies are somewhat atrophic." Final pathologic diagnosis was changes in the spleen indicating an increased venous pressure.

The postoperative course was essentially uneventful. Ascitic fluid drained from the abdominal wound for two weeks before the wound closed. The patient was discharged on the seventeenth postoperative day with only a small amount of ascites present. Two weeks later he was readmitted to the Urologic Service with acute postcatheterization cystitis due to staphylococcus. This cleared up rapidly with one week of sulfathiazole therapy. On May 10, 7500 cc of fluid was removed at paracentesis. Since then the patient has been seen in June, August and November 1943, also in March and November 1944. He experienced no further recurrence of ascites, hematemesis or melena. He gained strength and weight and has been able to hold a forty-eight-hour week defense job without difficulty, returning from work in the evenings so full of energy that he frequently takes his wife out to the movies or to dance! By August 1943 his blood count had returned to a perfectly normal level and it has remained normal ever since. The patient has continued to follow the Patek diet supplemented with yeast, choline and vitamin capsules ever since splenectomy. Although his liver remains palpably hard and nodular in the epigastrium, he is to all intents and purposes subjectively "cured" at the time of the present writing, nineteen months after splenectomy.

Comment—This 39 year old nonalcoholic man with severe cirrhosis of the liver either primary or secondary to Banti's splenic anemia, who had suffered from repeated hematemesis and recurrent ascites over a twenty-month period in spite of omentopexy, injection of esophageal varices, and a lengthy trial of the Patek regimen, made a dramatic recovery following splenectomy and has remained clinically well with no further ascites, hematemesis or anemia over a nineteen-month period since the removal of his spleen. It would appear that splenectomy was a life-saving measure in this particular instance. Since the liver was found to be about one-half normal in size at operation, the patient was impressed with the importance of continuing on the Patek diet supplemented with yeast and choline. He has followed this regimen religiously and is enjoying excellent health while holding down a full-time defense job at the present writing.

SUMMARY AND CONCLUSIONS

1 An abundance of experimental and clinical evidence points to dietary deficiency as a most important factor in the etiology of fatty liver and cirrhosis of the liver

2 Treatment of fatty liver and cirrhosis by a nutritious diet high in calories, protein and vitamins, especially the vitamin B-complex, appears to be the most promising form of therapy for this disease, even after signs of hepatic decompensation such as jaundice, ascites and hematemesis have developed.

3 This dietary treatment of cirrhosis has been discussed in some detail along with adjunctive therapeutic measures including various surgical procedures designed to relieve ascites and to prevent hematemesis.

4 Four cases are presented to illustrate the various aspects of dietary therapy. In one of these cases splenectomy was followed by dramatic relief from both ascites and hematemesis

THE USE OF SULFAMERAZINE IN PNEUMOCOCCAL PNEUMONIA

A GENECIN, M D * AND R A NELSON, M D †

THE desirability of discovering safer and more effective sulfonamide derivatives for the treatment of bacterial infections has led to the recent extensive trials of sulfamerazine by a number of investigators¹⁻¹² A methyl derivative of sulfadiazine, this drug has been shown to be very rapidly and completely absorbed after oral ingestion and relatively slowly excreted, thus making it possible to maintain adequate blood concentrations on smaller or less frequently administered doses Beta-hemolytic streptococcal, meningococcal and pneumococcal infections have already received extensive clinical trial with results which compare favorably with already well-tested sulfonamide drugs The preliminary studies seem to indicate that the toxicity of sulfamerazine is approximately the same as that of sulfadiazine

CASES INCLUDED IN THIS STUDY

Between January 1943 and June 1944, we have treated 292 cases of lobar pneumonia at the Johns Hopkins Hospital with sulfamerazine with gratifying results We believe that the cases which have come under our observation on the public wards are relatively severe infections For example, 20.9 per cent of the patients were found to have a blood stream infection with a typable pneumococcus at the time of entry Likewise, the incidence of involvement of more than one lobe is 31 per cent Many of our patients had other severe concomitant illnesses which are known to jeopardize the outcome of lobar pneumonia Approximately 15 per cent of the series were chronic alcoholics—a group of patients in whom multiple lobe involvement, bacteriemia, leukopenia, jaundice and delirium are especially apt to occur either singly or in combination Fifty-two patients were admitted with lobar pneumonia at the height of the influenza epidemic in December 1943 These patients were noted to have particularly virulent infections, often associated with leukopenia

A routine attempt to corroborate the clinical diagnosis with direct demonstrations of pneumococci in the sputum was made in almost all instances It is our impression that the direct capsular "quellung" procedure is of the utmost value in confirming the diagnosis of pneu-

† Associate in Medicine, Johns Hopkins University School of Medicine, Assistant Physician, Johns Hopkins Hospital

mococcal pneumonia at the earliest possible moment. Failure to obtain a direct typing from the sputum or from the inoculated mouse peritoneum should awaken a suspicion that the infection may not be primary lobar pneumonia and a re-evaluation of the patient's status is indicated. Thirty-four patients, many of whom had been treated with other sulfonamide drugs prior to entry, had no pneumococci in the sputum. These are included in the present series because the history and clinical course was otherwise typical of primary lobar pneumonia. We have not included influenzal, primary atypical, staphylococcal or streptococcal infections in the study.

PLAN OF TREATMENT

The plan of treatment was to give an initial dose of 4 gm. of sulfamerazine by mouth or 5 gm. of sodium sulfamerazine by vein, followed by maintenance oral doses of 3 to 6 gm. a day. In the early part of the study, thirteen of the more severe cases were given antipneu-

Fig. 47—Median whole blood concentrations of free sulfamerazine observed in 165 patients on a dosage of 3 gm. a day in 62 patients on 4 gm. a day, and 33 patients on 6 gm. a day.

mococcal rabbit serum as supplementary therapy, either because of initial grave prognosis or poor response to chemotherapy. As penicillin became more generally available later in 1943, twenty-two patients were given that drug in addition to full doses of sulfamerazine. Penicillin was given in doses of 20,000 units intravenously or intramuscularly every three hours.

Treatment with sulfamerazine was continued in all cases until forty-eight hours or more after the temperature and clinical response indicated satisfactory control of the infection. It was found that the period of time and total quantity of drug necessary to effect a cure was exceedingly variable. In general, many of those admitted early in the course of the disease had a prompt artificial crisis, but despite the temptation in these cases to discontinue therapy after two or three days, it was thought wiser to continue treatment until the risk of relapse was minimized. Treatment was promptly discontinued on suspicion of toxic reaction. Whenever possible, an oral test dose of 0.5 to 1 gm was given before hospital discharge where febrile and cutaneous sensitivity was suspected.

Blood sulfamerazine determinations were done at frequent intervals by the method of Bratton and Marshall. The median blood levels of free sulfamerazine (whole oxalated blood) on schedules of 3, 4 and 6 gm a day taken by mouth after an initial intravenous or oral dose are shown in Figure 47. As is to be expected, higher and better sustained levels are obtained with the more intensive schedules. With the passage of time, the daily median blood levels on all schedules decrease. On the 3 gm per day schedule, the daily medians vary between approximately 5 and 10 mg per 100 cc, on the 4 gm per day dosage, between 7.5 and 9.5 mg per 100 cc, and on the 6 gm per day, between 10.5 and 15.5 mg per 100 cc.

TOXIC REACTIONS

The toxic reactions which were encountered were of the same character and approximate frequency observed with other sulfonamide drugs in current use. In Table 1, there is presented an analysis of toxic manifestations in relation to dosage intensity. Fever and/or rash and renal irritation head the list of untoward effects. The rashes were similar to those seen with other sulfonamides, one of the patients developed an erythema multiforme-like syndrome with stomatitis, conjunctivitis and a papulovesicular eruption. Erythema nodosum was not seen. Two patients who developed urinary suppression, flank pain and hematuria were vigorously treated with forced fluids and alkalis and recovered promptly. The routine administration of alkalis in the form of sodium bicarbonate in large doses was not pursued. Although it would appear advisable to maintain a constantly alkaline urine, inconveniently large doses of sodium bicarbonate are necessary. Furthermore, many of the fatal renal reactions which are observed during sulfonamide administration are associated with a widespread toxic reaction in the tissues rather than simple mechanical obstruction by sulfonamide calculi. It is our impression that careful observation of the urinary output together with frequent urine examinations is adequate in most instances.

Nausea and vomiting were exceedingly rare. Delirium was com-

Totals	292	92	128	62	17	17	230	28	9	26 (8.9%)

monly observed in very ill patients, particularly alcoholics, but was not thought to be related to therapy in any instance. Despite the presence of the methyl group in sulfamerazine, no case of peripheral neuritis was observed, although all investigators have looked for an example of this reaction in view of the structural analogy with sulfamethylthiazole. Leukopenia, although frequent, was never alarming and there were no instances of agranulocytosis. Since the incidence of toxic reactions may be higher with the higher dosage schedules, we recommend a dose of 3 or 4 gm a day.

RESULTS

Analyses of groups of cases treated with sulfamerazine alone, sulfamerazine plus serum and sulfamerazine plus penicillin are presented. The relatively low incidences of involvement of more than one lobe,

concurrent illnesses and bacteriemia in the sulfamerazine group attests to the milder nature of these infections as contrasted with the selected groups of more seriously ill individuals who required supplementary treatment. The most unfavorable group prognostically was the penicillin treated, as is shown by the bacteriemic rate of 86.3 per cent (nine-

teen out of twenty-two) The case fatality rate of 27.3 per cent in this group seems to indicate that penicillin is at least as effective as serum, if not more so, as an adjunct to sulfonamide treatment

The course of treatment in a 66 year old white man with arteriosclerotic heart disease, myocardial insufficiency, bundle branch block, chronic alcoholic addiction and Laennec's cirrhosis with jaundice, who developed type III lobar pneumonia with bacteriemia is illustrated in Figure 48

In the entire series of 292 cases the case fatality rate was 8.9 per cent and the incidence of nonfatal complications was 15.4 per cent It should be mentioned that 15 of the twenty-six deaths occurred within twenty-four hours of entry The case fatality rate, excluding deaths within twenty-four hours after institution of therapy, is 4.0 per cent.

TABLE 3—COMPLICATIONS ENCOUNTERED IN 292 LOBAR PNEUMONIA PATIENTS TREATED WITH SULFAMERAZINE

	256 Cases Without Supplementary Treatment	36 Cases With Supplementary Treatment	Total
Living without complication	211 (82.5%)	10 (27.8%)	221 (75.6%)
Death	14 (5.4%)	12 (33.0%)	26 (8.9%)
Spread	9 (3.5%)	4 (11.1%)	13 (4.5%)
Pleurisy	9 (3.5%)	4 (11.1%)	13 (4.5%)
Empyema	2 (0.8%)	1 (2.8%)	3 (1.0%)
Thrombophlebitis	5 (2.0%)	2 (5.6%)	7 (2.4%)
Lung abscess	0 (0)	2 (5.6%)	2 (0.7%)
Pericarditis	0 (0)	1 (2.8%)	1 (0.3%)
Meningitis	0 (0)	1 (2.8%)	1 (0.3%)
Unresolved pneumonia	6 (2.3%)	2 (5.6%)	8 (2.7%)
Other	3 (1.2%)	3 (8.3%)	6 (2.1%)
Patients with death or complications	45 (17.6%)	26 (72.4%)	71 (24.3%)

Table 3 is a presentation of the distribution of complications encountered Approximately three quarters of all cases had a completely satisfactory outcome The more seriously ill patients, who required supplementary therapy, suffered a combined case fatality and complication rate of 72.4 per cent, whereas this figure for the sulfamerazine group is only 17.6 per cent Spread of the infection and the pleurisy

were observed as the most common complications. More serious complications were rare.

SUMMARY

1 An analysis of 292 cases of lobar pneumonia treated with sulfamerazine, either alone or in combination with antipneumococcal serum or penicillin, is presented

2 It is concluded that sulfamerazine is both a safe and effective chemotherapeutic agent in the treatment of lobar pneumonia

THIOURACIL AND HYPERTHYROIDISM

ELLIOT V. NEWMAN, M.D.*

THE discovery, experimental development and clinical application to hyperthyroidism of thiouracil has stimulated inquiry into the physiology of the thyroid gland and a hope that the disease can be controlled by medical treatment. Dissatisfaction with previous methods of treatment has been widely expressed. While proving a tremendous advance in the control of the disease and preparation of the patient for operation, iodization is not completely satisfactory. Though most patients respond well to iodine therapy, there are some who respond only partially and a few who do not respond at all. Furthermore, continuation of iodine treatment does not prevent exacerbations. It has been emphasized that the natural history of the disease is one of remissions and exacerbations, perhaps finally "burning itself out," which is not fundamentally altered by temporary control with iodine. Thus the usual course of treatment is to remove most of the gland surgically to effect a permanent remission^{1, 2}

Thyroidectomy has been adversely criticized for several reasons as a treatment for hyperthyroidism. Operative treatment is sometimes followed by complications or failures. Besides the small risk of anesthesia and usual complications of a surgical operation, there is the possibility of postoperative "thyroid storm." A rare case may result in parathyroid tetany or paralysis of the vocal cord. More serious is the late occurrence of undetected postoperative myxedema. But the greatest objection to surgical interference is that, somewhat like iodine treatment, it sometimes fails to cure the patient. Too often improvement after thyroidectomy is temporary and the disease reappears later. It thus pursues its "natural course" and produces an exacerbation, or "burns out" and causes myxedema.

In the "burning out" process the small amount of tissue left by the surgeon may become inadequate to maintain normal metabolism. Thus a patient who has thyroid disease must be considered a patient throughout his life because the manifestations of the disease are variable and protracted. Also there is a group of patients who may be made worse by operation, for it may precipitate a progressive increase in exophthalmos, resulting in ophthalmoplegia and disastrous ocular complications.

Lastly, there is the objection to thyroidectomy that it is a crude

* Instructor in Medicine, Johns Hopkins University School of Medicine, Resident in Medicine, Johns Hopkins Hospital

'unphysiological' method of attacking a disease, the pathological physiology of which has been extensively studied. In other words, it seems reasonable in the light of what is now known, that inevitably the treatment must be based upon more sound physiological and biochemical principles.

Granting that thyroidectomy is not a completely satisfactory treatment in the usual case, there are certain types in which operation is indicated. Very large goiters are removed because of cosmetic reasons and local constriction of other organs of the neck. Adenomas of the thyroid may be precancerous. Also, some patients because of mental or social factors may be unable to carry out any medical regimen. When serious toxic reactions occur, due to medical therapy, one must resort to operation.

With the advent of thiouracil in the treatment of hyperthyroidism, it was hoped that the disease could be controlled during the active stage throughout its history and that patients who required operation could be better prepared. From the standpoint of insight into the fundamental processes of the disease, thiouracil opened a new approach. It is interesting, therefore, at this time to review briefly the discovery, experimental development and clinical application of thiouracil in order to assess its place in the therapy of hyperthyroidism.

DISCOVERY AND EXPERIMENTAL DEVELOPMENT

Substances which produce goiter were known before the discovery of thiouracil. Rabbits fed a cabbage diet were found to develop huge glands.¹⁶ Thiocyanate administered to animals and to man occasionally produced enlargement of the thyroid.¹⁷ This type of goiter could be abolished by the administration of iodine.³

A new group of substances of which thiouracil is one whose action was *not* abolished by iodine administration was discovered in several ways. Kennedy and his associates found that a diet of Brassica seeds fed to animals caused a delay in growth, enlargement of the thyroid gland with hyperplasia of the epithelium and loss of colloid. The pituitary glands of these animals showed increase in basophil cells. The hyperplasia could be abolished by hypophysectomy or by administration of thyroid extract, but not by iodine. Later Kennedy reported that allylthiourea produced the same changes.^{4, 5}

Also Richter noted when feeding phenylthiocarbamide to rats that prolonged dosage caused enlargement and hyperplasia of the thyroid.⁶ At about the same time the Mackenzies while testing the antibacterial effects of sulfonamides on rats found incidentally that there was great enlargement of the thyroid glands. Subsequent investigation showed that sulfonamides and thiourea compounds all produced lowering of the basal metabolic rate, enlargement of the gland with loss of colloid, increase in the height of the epithelium and 'thyroidectomy' cells in the pituitary gland. The effects on the thyroid gland were

abolished by thyroxin administration, hypophysectomy, but *not* by giving iodine ⁷

Further work on the mechanism of action on the thyroid gland of the sulfonamides and thiourea compounds by Astwood finally led to the selection of thiourea and thiouracil for clinical use in the treatment of hyperthyroidism ^{8, 9} Astwood tested over one hundred related compounds of different chemical structure to compare their activity and toxicity. The compounds fell into two groups, (I) the thiourea derivatives and (II) the aniline derivatives. The chemical structure essential for activity in Group I was $\text{HN}-\text{CS}-\text{NH}_2$, for Group II, $\text{NH}_2-\text{C}_6\text{H}_4$. The entire structure of the first group was necessary, activity was lost if the S or either NH radical was replaced. In Group II the amino group must be free. The most active substance in Group I was thiouracil, in Group II the aminobenzoic acids.

The formula for thiouracil is,

From these earlier investigations a theory of the mechanism of action of thiouracil was derived. It was postulated that thiouracil interferes with the manufacture of thyroid hormone by the gland. This resulted in a diminished secretion of hormone which was followed by lowering of basal metabolic rate, failure of growth and development, and lowered food intake. Reduction of the secretion of thyroid hormone elicited an increased output of pituitary thyrotropic hormone with histologic changes in the pituitary. Thyrotropic hormone then stimulated the thyroid gland, causing hyperplasia with heightening of the epithelium and enlargement, and loss of colloid. A rather paradoxical picture of a myxedematous animal with a highly overactive appearing thyroid gland is the result of the chain of events initiated by the action of these drugs ^{10, 11, 12, 13, 14, 15}

Since the work on the primary metabolic and histologic effects of thiouracil and related compounds there has been much experimental data on the metabolism of iodine in the thyroid gland in the intact organism and in isolated tissue. The level of protein bound iodine in plasma is known to be correlated closely with the basal heat production of the organism ¹⁶. In hyperthyroidism the level is elevated and after treatment with thiouracil the level falls, demonstrating directly the lowering of the amount of hormone due to the drug. The mechanism within the thyroid gland whereby the hormone production is depressed has not been completely elucidated. Studies with injections of radioactive iodine have shown a marked inability of the thiouracil treated gland to utilize the iodine, most of the iodine being excreted in the urine. The concentration of iodine found in the gland after

administration of thiouracil is very low. This result is in contrast to the normal gland which takes up considerable quantities of administered iodine, and it is in marked contrast to the glands made goitrous with thiocyanate which have a great avidity for administered iodine. Not only is there a decreased uptake of iodine by the gland, but the conversion of iodine to diiodotyrosine or organically bound iodine is markedly depressed. This has been demonstrated in the intact gland and in tissue slices. In tissue slices, however, the iodine concentrating power may not be depressed although conversion to hormone is greatly inhibited.^{19 20 21, 22, 23 24 25 26}

The marked decrease in iodine in the thyroid glands due to thiouracil is promptly reversible within one to two weeks after discontinuing the drug. That the decrease in iodine in the gland was due to thiouracil and not to thyrotropic hormone is shown by the relatively small loss of iodine after large injections of thyrotropic hormone.

The exact mechanism of action of thiouracil in the thyroid gland has not yet been elucidated. It was demonstrated in vitro that thiouracil inhibits the peroxidase activity in thyroid tissue which would interfere with the conversion of diiodotyrosine to thyroxine.²⁷

There are interesting observations on other effects of thyroid hormone, iodine, thiouracil and thyrotropic hormone, and of the modifying action of one substance on the other. This may have bearing on the therapy in hyperthyroidism since more than one form of therapy may be given simultaneously or one may follow the other. Thyrotropic hormone given with thiouracil enhances the goitrogenic effect. Thyrotropic hormone alone causes marked enlargement of the thyroid gland but causes relatively little loss of iodine from the gland. Potassium iodide inhibited the colloid depleting effect of thyrotropin where thyrotropin was given alone or in conjunction with thiouracil. This effect of potassium iodide may be of therapeutic value since a gland with more colloid may be firmer and easier to remove surgically.

The influence of thyroid hormone and potassium iodide upon the storage of thiouracil in the thyroid gland has been investigated. Thyroid hormone decreases thiouracil storage, whereas potassium iodide greatly increases storage of thiouracil in the gland. It has been suggested that iodine administration might enhance the effect of thiouracil because of increased storage of thiouracil.^{28 29 30}

One might reasonably expect that a combination of iodine and thiouracil would cause a more rapid fall in basal metabolic rate than either alone, since both will cause a rapid remission of hyperthyroidism and a fall in blood hormonal iodine. However, it appears that there is a maximum rate at which metabolism can be lowered by attacking the thyroid gland either chemically or surgically. Means observed that the maximum rapidity of decline of the basal metabolic rate is the same whether the patient with hyperthyroidism is iodinated or thyroidectomized, or when the myxedematous person is allowed to decay. In

one person identical curves of decline in metabolism were produced by iodination when the person was spontaneously thyrotoxic and by cessation of thyroid administration when she was artificially thyrotoxic. From these facts it seems apparent that there is a definite limitation to the rapidity of response of a thyrotoxic individual no matter what therapy be used. The gland may be cut off physiologically or surgically and whatever hormone remains in the body requires a definite time to catabolize. According to this view, iodine administration stops delivery of hormone from the gland to the body, but does not cause storage in the gland of hormone already secreted. It is not likely, therefore, that thiouracil alone or in combination with other drugs will cause a lowering of metabolism faster than the normal catabolism of thyroid hormone will allow.³¹

CLINICAL APPLICATION OF THIOURACIL

Pharmacology—The absorption, distribution and excretion of thiouracil has been studied by Williams, Weinglass and Kay.³² Absorption from the gastrointestinal tract is very rapid. The blood level rises within the first hour after a single dose of 0.2 gm. and falls steadily and is very low after eight hours. Thereafter a small amount is present for two days. When 0.2 gm. were given every four hours for three days the blood level remained fairly constant after twenty-four to forty-eight hours at 2 to 3 mg. per 100 cc. of blood. With oral administration of a total of 0.2 to 1.2 gm. a day given in doses of 0.2 gm. at evenly spaced intervals, the blood level ranged from 0.8 to 6.4 mg. per 100 cc. Most of the drug is carried in the red blood cells. The renal excretion remains relatively constant during this period. Destruction of some of the drug occurs in the gastrointestinal tract and some by the rest of the body. No thiouracil is excreted in the stools. It does not accumulate to any great extent in the body even in a patient with nephritis or cirrhosis of the liver because many tissues can apparently destroy the drug. The drug is distributed throughout all body tissues that have been examined at autopsy. Relatively large quantities were sometimes present in bone marrow, thyroid, ovaries and pituitary. In two patients with nodular thyroid glands removed at operation the analyses of the adenomatous tissue showed markedly higher concentration of thiouracil than the surrounding relatively normal tissue.

It is apparent that the rapidity of absorption and excretion of the drug requires that it be given in divided doses throughout the day. The dose used for clinical purposes has been from 0.1 to 1 gm. per day. The usual practice is to give 0.6 gm. per day for a few weeks or until the metabolism is controlled and then maintain the patient on 0.1 to 0.4 gm. per day. Evidence has been presented that the daily maintenance dose must be adjusted to the individual since some may not be controlled by low dosage, while others may develop signs of myxedema on larger amounts.

Toxicity—Animal experimentation has shown thiouracil to be relatively nontoxic. Examination of patients who were given thiouracil before death showed no gross or microscopic pathological lesions attributable to the drug^{33 34}

Clinically, however, a variety of toxic effects have been noted, the most serious being *leukopenia* or *agranulocytosis*. Scanning the reports in the literature at present available, there were toxic reactions noted in forty-seven of 377 patients (12 per cent) who received the drug. The most common reactions were fever in fourteen cases, leukopenia in thirteen cases, urticaria or other rashes in eleven cases, and agranulocytosis in five cases. Several patients had combinations of symptoms such as rash, fever and agranulocytosis, or rash and fever. Miscellaneous toxic reactions, some of which were questionably due to thiouracil, were headache, jaundice, enlarged lymph glands, diarrhea, enlarged salivary gland, arthralgia, dental abscesses, gastric distress, nausea vomiting and chills. In one case there was hemorrhage into the thyroid gland supposedly caused by increased vascularity due to thiouracil. A few cases of edema of the legs were reported which might have been due to a salt-retaining effect of thiouracil. In addition, under the heading of toxicity might be listed several cases which showed signs of hypothyroidism on higher maintenance dosages.

Practically all the toxic reactions were found to subside on discontinuing the drug. It was the experience of many investigators that some milder reactions would subside without discontinuing the drug. Also, many reactions did not recur on resuming therapy.

The one toxic effect which has proved very serious and warrants complete cessation of thiouracil therapy is neutrophilic leukopenia or agranulocytosis. Deaths from agranulocytosis have occurred. The attention of clinical investigators has been brought to the fact that thiouracil has been given in about 2000 cases and there have been at least seven fatalities from agranulocytosis. This result imposes certain limitations on the use of the drug. Many other cases of agranulocytosis have occurred but the patients have recovered on the withdrawal of thiouracil³⁵⁻³⁶

The toxic reactions resulting from thiouracil are similar to those complicating sulfonamide therapy. In this connection it is interesting to note the work of Sebrell and his co-workers on the prevention of experimental agranulocytosis in rats given sulfonamides with liver preparations³⁷. More recently Goldsmith has found that the neutrophilic leukopenia obtained by feeding thiourea to rats could be prevented by simultaneous feeding of a solubilized liver preparation³⁸. One might wonder whether further information obtained on the mechanism of thiouracil and sulfonamide agranulocytosis might not obviate this most serious objection to the use of these drugs.

It is obviously of paramount importance in the treatment of a patient with thiouracil to observe closely the total white cell and dif-

ferential count of the blood Difficulty in interpretation of the values may arise because of the tendency of hyperthyroid patients to have a slight leukopenia with a low percentage of neutrophils It would seem a wise policy to follow the leukocyte count at daily intervals if the total count is as low as 4000 or the differential count shows a fall of neutrophils to 40 per cent, and to discontinue the drug if the total count declines to 3500 or the differential to 30 per cent neutrophils

*Results of Treatment—Prolonged Treatment without Operation—*Very few reports are available on the preoperative preparation of patients with thiouracil Most of the cases are treated without operation in the hope that by controlling the disease as long as it is active a permanent remission may finally be obtained It is apparently too early to judge the success of this procedure since cases have been followed for relatively short periods Of great concern in the long term treatment is the possibility of toxic reactions and the necessity of close observation It is generally agreed that the disease can be controlled as long as the drug is used in adequate doses Exacerbation of the disease is the rule when thiouracil is discontinued However, Astwood has reported nine cases of sustained remissions for as long as two to nine months after discontinuing therapy³⁷

*Preoperative Treatment with Thiouracil—*Regardless of whether long term treatment is practicable, it seems fairly certain that thiouracil will have a definite place in the preparation of the thyrotoxic patient for operation The completeness and certainty of the response to thiouracil, and the depletion of a thyroid gland of hormone at the time of operation, are practical advantages

A series of patients with thyrotoxicosis were prepared for operation with thiouracil at the Johns Hopkins Hospital in order to determine its usefulness Previously it had been the policy to prepare patients for operation on the Medical Wards by iodization and routine supportive measures The patient was then transferred to the Surgical Service when, in the combined judgment of both physicians and surgeons, the patient was adequately prepared This policy was continued with thiouracil preparation

So far thirty-four consecutive cases have been treated Twenty-nine patients had diffuse toxic goiters, four had adenomatous glands and one had carcinoma proved by histological examination

The patients were given a high vitamin, high caloric diet Small doses of phenobarbital were used for sedation Respiratory isolation was usually maintained Before specific therapy was begun two basal metabolic rate determinations were obtained The course was followed by studies of the metabolic rate and by determination of blood cholesterol once or twice weekly The weight, general symptomatology, and size and consistency of the thyroid gland were noted Leukocyte counts and differential counts were done twice weekly and more often if slightly below normal In most cases, through the cooperation of

the ophthalmological service, the degree of exophthalmos was measured objectively with the exophthalmometer before the treatment and after operation.

The first six cases were prepared with thiouracil alone, thereafter patients received thiouracil and iodine simultaneously. The usual dose of thiouracil was 0.6 gm. daily, divided in three doses throughout the day. Iodine was given in the form of Lugol's solution 1.5 cc. daily at different times than the thiouracil. Drug therapy was discontinued the day of operation.

Decision about the preparedness of the patient depended upon the subsidence of symptoms such as nervousness and weakness, upon the subsidence of the metabolic rate, the gain of weight, rise in cholesterol and diminution of the tachycardia. While there is great interest in the rate of fall and extent of fall of the metabolic rate under treatment, the general condition of the patient and other signs were equally important criteria in the decision.

The average metabolic rate of the patients before drug therapy was plus 55 per cent (range plus 14 to plus 90). After an average of twenty-six days (range ten to forty-four days) of thiouracil (with or without iodine) the metabolic level averaged plus 18 per cent (range minus 8 to plus 35). Within five to ten days after operation the average metabolic rate was plus 9 per cent (range minus 25 to plus 25).

Although the average duration of drug therapy was twenty-six days the patients remained in the hospital for longer periods. From two to seven days were required for control observations before treatment. The patients were discharged from the hospital within five to ten days after operation to be followed in the dispensary.

Weight gain was usually steady beginning within a few days of treatment. Nine patients showed no gain or loss. The average weight gain for all patients was 6 pounds (range 0 to 20). Frequently a loss of several pounds occurred in the first few days after admission to the hospital. This is interpreted as a loss of water at bed rest.

A fairly steady fall in the pulse rate took place with treatment. The average of the daily maximum and minimum pulse rate from four-hour charts were plotted and the fall in pulse level was estimated from the graphic curves. The average drop in pulse rate was 14 points (range 0 to 30). Only two patients failed to show a significant fall in pulse rate.

Blood cholesterol rose in a consistent curve as the metabolic rate fell. The average increase of the blood cholesterol over the level obtained before treatment for all patients was 79 mg. per 100 cc. (range 0 to 200 mg.). Four patients failed to show a significant increase.

Serious difficulty with leukopenia or agranulocytosis was not encountered. The average of the lowest leukocyte counts for each patient was 5968 per cu. mm. Seven patients had counts at some time below 5000 but only one patient fell below 4000. No dangerously low percentages of granulocytes occurred.

Objective measurements of the degree of exophthalmos and particularly of any change in exophthalmos under therapy are important because of the possibility of precipitating progressive exophthalmos. Measurements by exophthalmometer were taken in eighteen patients before treatment and in ten patients both before and after treatment. There were no marked increases or decreases in exophthalmos. The changes were within 1 to 3 mm of exophthalmos. Six of the ten patients showed a decrease with treatment, but on the whole the magnitude of the changes were not definitely significant.

Care was taken to anticipate progressive exophthalmos because of other reports of its occurrence with thiouracil and the danger of thyroidectomy in such cases. Excellent descriptions and discussion of this complication of hyperthyroidism have recently been given. Mulvany has recently presented the subject of exophthalmos of hyperthyroidism and the mechanism, pathology and symptomatology of two varieties which he terms "thyrotoxic exophthalmos" and "thyrotrophic exophthalmos," the latter being the "progressive" or "malignant" type which leads to ophthalmoplegia. The fact that the exophthalmometer measurements in the cases in our study remained stationary or tended to diminish is evidence that those cases were of the "thyrotoxic" variety which according to Mulvany are made worse by thyroid hormone, whereas the thyrotrophic variety is improved by thyroid hormone.^{59, 60, 61, 62}

Effect of Iodine Administration before and during Thiouracil Therapy—The general experience seems to be that previous iodine administration delays the response to thiouracil. Astwood reports some delay but the effect was not consistent.⁸⁷ In the present series seven patients had had iodine treatment up to the time of, or to within two weeks before thiouracil therapy. While some of the patients showed a delayed response to thiouracil, the delay was no greater than observed occasionally in patients who had had no iodine previously. Some of the iodine treated patients responded as rapidly as those previously untreated.

The first six patients treated with thiouracil alone proved at operation to have very vascular and friable glands. This led to difficulty in handling the gland and obtaining hemostasis.⁵⁸ Because of this unsatisfactory aspect of thiouracil preparation the remainder of the patients were given iodine and thiouracil simultaneously. Since that time the glands have been generally firmer, less vascular and easier technically to remove.

Postoperative Course—In no case was there any serious operative or postoperative complication attributable to an increase or an exacerbation of thyrotoxicosis. In nineteen of thirty-four cases the temperature and pulse were equal to or below the preoperative levels within twenty-four hours after operation. In the remaining fourteen cases slight temporary temperature elevations occurred. No patients had fever for

more than forty-eight hours after operation. Fever was most frequently associated with hoarseness and tracheobronchitis. No other causes of fever could be found. Elevations of pulse rate out of proportion to the temperature rise did not occur. One patient developed a hematoma in the wound which subsided uneventfully. Two patients developed unilateral vocal cord paralysis, one of which subsequently remitted. One patient had hypocalcemia which was controlled by calcium administration. On the whole the postoperative course of these patients was uneventful and entirely satisfactory. Follow-up of the patients after discharge from the hospital is still in progress.

ILLUSTRATIVE CASES

A few illustrations of the preoperative and postoperative course of these patients are appended. Operations were performed by Dr. Alfred Blalock, Surgeon in Chief, and the Resident Staff, Drs. Kenneth L. Pickrell, William P. Longmire, Jr., Herbert E. Sloan, Jr., and George W. Duncan. Pathological sections were examined by Dr. Sam S. Blackman, Jr., Associate Professor of Pathology. The author is indebted to Dr. Alfred Blalock for advice and encouragement, and permission to use the surgical records. Thiouracil was supplied by the Lederle Laboratories, Pearl River, New York.

Case 1 Preparation with Thiouracil Alone in a Patient Who Had Previously Received Iodine

C. S., a 25 year old colored woman, was admitted on December 10, 1943 with the chief complaints of nervousness and swelling in neck for several months.

The present illness began with insomnia a year before admission. The patient noticed nervousness and a tremor of the body for five months. There was an increase in appetite but a weight loss of 18 pounds in six months. Her physician gave her Lugol's solution, 10 drops daily for six weeks, until two weeks before admission, and because of lack of improvement in symptoms she was sent to the hospital.

Physical examination on admission showed a thin colored female who was very excitable and fidgety. The temperature was 100° F., the pulse 140, respiration 24 and blood pressure 130/60. The skin was warm and moist. Exophthalmos was visible, and there was slight lid lag and edema of the upper lids. The thyroid gland was visibly and palpably diffusely enlarged, soft with a palpable and audible bruit. The lungs were not remarkable. The heart showed slight enlargement to the left with a rapid rate and a soft systolic precordial murmur. Abdominal, pelvic and rectal examinations were not remarkable. There was a fine tremor of the hands and feet.

Laboratory examinations showed a negative serological test for syphilis. Blood red cell count was 3.8 million, hemoglobin 12.5 gm., hematocrit 39 per cent cells. After treatment these rose to 5 million red cells, 13.6 gm. hemoglobin and 43 per cent hematocrit. Leukocytes remained between 7400 to 12,000 with normal differential counts. Urine and stool examinations were not remarkable.

Other studies were: venous pressure 110 mm. of saline; circulation time (arm to tongue) 8 seconds; chest plate—lungs clear; heart slightly enlarged to left; urea clearance 70 per cent of normal; electrocardiogram not remarkable except for tachycardia.

Exophthalmometer measurements were before treatment—right 22 mm., left 22 mm., after treatment—right 22 mm., left 20 mm

The patient's course is illustrated by the chart (Fig 49) There was loss of nervousness, tremor and weakness No significant change in the size of the thyroid gland was noted, but it seemed to be more firm after treatment

Fig 49—Clinical course in Case I

Subtotal thyroidectomy was carried out. The procedure was extremely bloody. It was difficult to maintain hemostasis because of the marked vascularity and friability of the gland. The operative field was dry at the end of operation, however, and the patient returned to the ward in good condition. Because of loss of blood at operation and fall in blood pressure, she was given a transfusion during operation and another on return to the ward. In the afternoon after operation the pulse was 76 and blood pressure 122/78. Thereafter the course was uneventful except for some hoarseness and soreness at the operative site.

Pathological examination of the removed tissue showed very marked and diffuse hyperplasia with tall columnar cells with loss of colloid. The weight of the removed thyroid tissue was 100 gm. In many places the acini were completely occluded by overgrowth of cells. The gland had the appearance of an untreated case before the days of iodine preparation.

Case II Preparation of Patient with Iodine and Thiouracil Simultaneously, Who Had Not Received Iodine Previously

C. N., a 33 year old white woman, was admitted with the chief complaints of weakness, nervousness and palpitations for three weeks.

Fig 50—Clinical course in Case II

Past history reveals that six years ago she developed weakness, tiredness, weight loss and nervousness. Enlargement of the neck and prominent eyes were noted. She had a subtotal thyroidectomy at that time in North Carolina. She experienced great improvement and continued in good health until one year ago.

Present illness began about one year ago with fatigue and instability of emotions. She became suddenly much worse three weeks before admission with weakness, palpitation, nervousness and attacks of profuse sweating. Also there had been several attacks of "weakness and numbness" in the extremities, lasting about five minutes.

Physical examination on admission showed a temperature of 99.6° F., pulse 110 and blood pressure 135/72. The patient was a thin nervous woman with prominent staring eyes. The skin was moist. The lid slits were widened. The thyroid gland was diffusely enlarged on both sides and moderately firm with no audible bruit. Scar from previous operation was present. The lungs revealed only slight dullness at the left base. The heart showed a systolic murmur over the precordium and tachycardia. The size was normal. The abdomen was not remarkable. The extremities had overactive reflexes.

Laboratory examinations revealed a normal blood cell picture. The leukocyte counts remained between 7050 to 9800. Urine examinations were normal.

Other studies were x-ray and fluoroscopy of chest—slight thickened pleura in left lower lung fields, normal cardiac outline, no substernal thyroid, venous pressure 95 mm saline, circulation time (arm to tongue) 8 seconds.

Exophthalmometer readings were 21 and 18 mm on the right and left eyes before treatment, and 18 mm in both eyes after treatment.

The patient had a temperature elevation to 103° one day which was unexplained and subsided rapidly. Although the basal metabolic rate (Fig 50) did not fall below plus 25 per cent, the other signs of improvement were dramatic with the gain in weight, increase in blood cholesterol and the slowing of the pulse rate. The patient felt much improved. The gland became firmer.

Operation was somewhat difficult because of scarring due to the previous operation. The gland was firm and gray and did not bleed profusely. The patient stood the procedure well. The tissue removed weighed 88 gm.

The postoperative course was uneventful except on the fourth hospital day when the patient complained of numbness and tingling in the extremities. Blood calcium was 7.0 mg per 100 cc. She was given calcium chloride and calcium lactate by mouth. The paresthesias disappeared and the blood calcium level was 8.3 mg per 100 cc on discharge.

Pathological examination of the tissue showed many acini filled with colloid with cells of low cuboidal type. Other areas were quite hyperplastic with high columnar cells.

Case III Adequate and Uncomplicated Response to Simultaneous Iodine and Thiouracil Therapy No Previous Iodine

E. J., a 50 year old colored woman, was admitted with the chief complaint of a goiter of three years' duration.

The present illness started with people calling her attention to swelling of the neck three years ago. It caused no symptoms. A year ago she noticed nervousness, increase in appetite and weight loss. She had swelling of the ankles after long standing and became quite weak. The symptoms gradually became worse and she lost 45 pounds. Dyspnea on moderate exertion developed.

Physical examination showed a temperature of 100.2° F., pulse 128 and blood pressure 144/64. The patient looked emaciated, was fidgety and apprehensive. The skin was warm and moist, especially the palms and soles. The eyes showed poor convergence and lack of wrinkling of forehead on upward gaze. The neck showed a markedly enlarged thyroid, firm and slightly nodular. The lungs were clear. The heart was enlarged to the left with a visible precordial pulsation. There was a loud systolic murmur over the precordium and at the apex. Abdominal examination revealed the liver palpable one fingerbreadth below the costal

margin Pelvic and rectal observations were normal There was a tremor of the hands.

Laboratory work showed a normal blood cell picture, the leukocytes remaining between 8200 to 11,000 The urine was normal

Other studies were x ray of chest—the heart was enlarged mostly to the left, lungs clear no substernal thyroid total serum protein 6.31 gm per 100 cc.; electrocardiogram—normal record except for tachycardia

Fig 51—Clinical course in Case III

Exophthalmometer measurements were 20 mm right, 21 mm left before treatment 20 mm right, and 18 mm left eye after treatment

The patient's course was one of steady improvement (Fig 51) The thyroid gland seemed to become definitely smaller under treatment

At operation a firm, whitish gland was found No technical difficulty was encountered The postoperative course was entirely uneventful except for a

period of one-half hour during the first day when the pulse was said to be 110 and irregular. This apparently subsided spontaneously and the pulse was 85 per minute six hours after operation.

Pathological examination of the removed tissue showed *diffuse moderate hyperplasia*. There was no adenoma. The tissue weighed 55 gm.

Case IV Preparation with Thiouracil for Thirty days and Iodine in Addition for the Last Fifteen Days

E. P., a 44 year old colored woman, was admitted with the chief complaints of "goiter," weight loss and nervousness.

Fig 52—Clinical course in Case IV

The present illness began about six months before admission with nervousness, sleeplessness and feeling warm all the time. Swelling of the neck was noted for four months, and her eyes became prominent. Weakness in the legs became marked. Appetite was increased. She lost 27 pounds in the course of the illness.

Physical examination showed a temperature of 98.6 F., pulse 98 and blood pressure 184/90. The patient was moderately well nourished but nervous and "jumpy" with quick speech and spontaneous laughter. The skin was warm and moist. The lid slits were widened but no other eye signs were made out. The tonsils were large. The thyroid gland was diffusely enlarged to about three times normal size. It was soft and a bruit was heard. The lungs were clear. The heart seemed enlarged to the left. There were soft systolic murmurs at the apex and pulmonic areas. Abdominal, pelvic and rectal examinations were not remarkable. Reflexes were hyperactive and a fine tremor of fingers was present.

Laboratory examinations showed a normal blood cell picture. The leukocyte count remained between 6300 and 12 000. Urine examinations were normal.

Other studies were: venous pressure 80 mm. of saline, circulation time (arm to carotid sinus) 14 seconds, x ray of chest—the heart was within normal limits, lungs were clear except for small calcified area probably in the pleura, electrocardiogram—record suggested left sided enlargement and "strain."

Exophthalmometer measurements were 15 and 16 mm. in the right and left eyes before treatment and 16 and 17 mm. after treatment.

The patient's course is shown in Fig. 52. The temperature elevations were thought to be due to pharyngitis and tonsillitis. Throat cultures showed beta hemolytic streptococci and there was some white exudate on the tonsils. This cleared up with sulfadiazine throat spray. The patient became much less jittery with treatment. No change was noted in the thyroid gland.

At operation the gland was diffusely enlarged. Hemorrhage encountered was marked but not extreme. The postoperative course of the patient was uneventful. She complained of some hoarseness and discomfort at the site of operation. A small amount of bloody fluid was aspirated from the wound.

Pathological study of the removed tissue showed marked hyperplasia, with many areas of infolding of tall columnar epithelium with almost no colloid in the acini. The weight of the tissue removed was 33 gm.

Case V. Thiouracil Treatment after Demonstrated Failure to Respond to Iodine, with Febrile Reaction

H. D., a 47 year old colored woman, was admitted with the chief complaints of "jittery feeling," lump in neck and weight loss for six months.

Past history revealed that she had a large goiter removed twenty years ago at another hospital. She apparently had no symptoms of hyperthyroidism at that time. She was asymptomatic until the present episode.

The present illness began six months before admission with feeling of weakness and tiredness. For the last month she had been very nervous. Appetite remained good, but she lost 20 pounds in six months. She noticed a swelling in the neck. Four months ago her physician gave her Lugol's solution, ten drops three times a day for two weeks with some relief but she has had no treatment since.

The patient was first seen in the medical dispensary where a diagnosis of hyperthyroidism with a nodular goiter was made. She was admitted to the surgical service and placed on iodine therapy for two weeks (Fig. 53). Because of complete lack of improvement symptomatically and physically she was transferred to the medical service for thiouracil preparation.

Physical examination showed a temperature of 98.7 F., pulse 90 and blood pressure 136/80. The patient squirmed and fidgeted about the bed. The skin was loose, moist and warm. The eyes did not appear prominent and the lid slits were not wide, but there was some edema of the lids. The neck showed an old operative scar. The thyroid gland was diffusely enlarged on the right side, but slightly nodular. The left side showed a nodule the size of a small egg. The lungs were clear. The heart was enlarged to the left, the point of maximum

impulse being 8 cm to the left in the fifth interspace. There were systolic murmurs at the apex and pulmonic areas. Abdominal, pelvic and rectal examinations revealed no significantly abnormal findings. A fine tremor of the hands and quite active reflexes were present.

Laboratory work showed a normal blood cell picture. Leukocytes remained between 6000 to 7200. The urine was normal.

Other studies were: venous pressure 140 mm of saline, total serum protein 7.7 gm per 100 cc, throat culture—normal throat flora, urine culture—sterile,

Fig 53—Clinical course in Case V

blood culture at the time of fever—no growth, electrocardiogram—normal record except for tachycardia, x-ray of chest—lungs clear, heart enlarged, no evidence of substernal thyroid.

Exophthalmometer measurement in the course of treatment was 21 mm in both eyes.

The patient's course is illustrated by the chart. It was complicated by the development of fever which subsided on discontinuing thiouracil and recurred slightly on giving a small dose. Thiouracil was resumed again after three days.

and no fever was encountered. Although the basal metabolic rate had fallen from the previous level of plus 40 per cent to only plus 25 per cent, because of the patient's general symptomatic improvement and beginning weight gain and rise in cholesterol with a lowering of the pulse and blood pressure (to 100/66) she was considered by both surgeons and physicians to be in adequate condition for operation.

At operation there was much scarring from previous operation. The gland showed the gross characteristics of hyperplasia. With some difficulty many bleeding points were controlled and the wound was finally dry. The patient withstood the operation well.

The postoperative course was entirely uneventful. There was hoarseness for two days but the voice was normal at the time of discharge. Convalescence was carried out on the medical wards with improvement in nervousness and rapid weight gain.

Pathological examination of the removed tissue showed fetal and Hurthle cell adenomas. The adenomatous areas had small acini with little colloid and marked hyperplasia. The surrounding thyroid tissue showed marked hyperplasia with marked variation in the size of the acini and the amount of colloid in them. The weight of the removed tissue was 57 gm.

Case VI Simultaneous Thiouracil and Iodine Preparation in a Male Patient with Exophthalmos

J. D., a 35 year old white man was admitted with the chief complaint of nervousness of ten months' duration.

The present illness began with weight loss and craving for carbohydrate food. For five months the patient noted nervousness and for two months had palpitation at rest or on slight exertion. A few weeks ago friends commented on prominence of his eyes. Strength remained good. He lost 50 pounds in the course of the year. He had not received any medication.

Physical examination showed a temperature of 100.6 F., pulse 120 and blood pressure 160/70. The general appearance was of a thin, nervous person who talked rapidly and fidgeted with his hands. The eyes were very prominent. The sclerae were visible below the cornea but not above. There was mild diffuse injection of the conjunctivae. The lids were normal and the tension normal to digital pressure. Exophthalmometer readings: right eye 23 mm., left eye 22 mm. Tonsils were huge and injected. The thyroid gland was diffusely enlarged, soft with a slight bruit over entire region. The heart size was normal to percussion with a late systolic whistling murmur at apex. The lungs were clear. Abdominal, genital and rectal examinations were normal. There was a marked tremor of the hands.

Laboratory examinations showed a normal blood cell picture. Leukocyte counts remained between 7600 and 10,000. Urine was normal except for 2 plus sugar on one occasion.

Other studies were: x ray of the chest—heart and aorta normal, lungs clear; no substernal thyroid; fasting blood sugar 93 mg. per 100 cc., electrocardiogram—high P waves and tachycardia; total serum protein 6.0 gm. per 100 cc., throat culture—normal throat flora.

The patient's course is illustrated by the chart (Fig. 54). He became less nervous and felt much stronger. He frequently complained of soreness and tenderness in both nipples which off and on had tender nodules in the areolar area and were slightly swollen. The patient's exophthalmos caused some concern since with treatment the right eye seemed to become more prominent. Exophthalmometer measurements remained at 22 mm. in the left eye but increased from 22 to 25 mm. in the right eye. Examination by Dr. Frank B. Walsh showed slight fullness of the lids and possibly low grade edema of the conjunctiva. The

eyes were easily pushed back into the orbits. It was Dr Walsh's opinion that the patient presented only minimal signs which might suggest that he would develop progressive exophthalmos. The patient was followed closely in regard to his eyes because of the relatively much higher frequency of progressive exophthalmos in males than females with hyperthyroidism.

Subtotal thyroidectomy was carried out. The gland was quite firm and no technical difficulty was encountered. The postoperative course was complicated

Fig 54—Clinical course in Case VI

by a marked hoarseness and cough with temperature elevation to 101.0° F for two days. This was thought to be due to laryngitis and tracheitis. The vocal cords were slightly thickened. The chest plate showed the lungs clear. Sulfamerazine was given for a few days and the symptoms and fever subsided. The remainder of the convalescence was uneventful.

Pathological examination of the tissue removed at operation showed generally slight to moderate hyperplasia. In some small foci there was marked hyperplasia.

Most of the acini were fairly large and filled with colloid. The removed tissue weighed 71 gm.

MEDICAL MYCOLOGY

EDMUND L. KEENEY, M D *

It is the purpose of this clinic to discuss the common fungous diseases and point out some of the significant and the recent contributions made for each disease. For the sake of clarity and of convenience the various superficial mycotic infections will be discussed together under the heading of "dermatophytosis" and the deep-seated mycotic infections will be taken up individually.

DERMATOPHYTOSIS

Dermatophytosis is a more or less superficial infection of the skin, the hair and the nails caused by any one of the fungi known as the dermatophytes. The fungi included in the genera of *Trichophyton*, *Epidermophyton*, *Microsporum* and *Candida* (*Monilia*) are referred to as the dermatophytes. These parasites may infect many different body regions and have a wide range of morbid anatomical expressions. It is because of these two latter characteristics that so many confusing terms have invaded the literature. *Tinea*, which means "worm," precedes *pedis*, *capitis*, and *cruris* on occasions to denote the region of the body infected and then on other occasions is used before *circinata* and *imbricata*, to describe an anatomical expression of the infection.

Only one or two species of each of the genera referred to above are of clinical importance. *Trichophyton mentagraphytes* and *Trichophyton rubrum* commonly infect the skin and the nails of the feet, *Epidermophyton floccosum* commonly infects the skin of the groin, *Microsporum audouini* and *Microsporum felineum* commonly infect the hairs of the scalp in children, and *Candida albicans*, which may also produce deep-seated lesions, commonly infects the mucous membranes of the mouth (thrush) and the vagina.

Diagnosis.—Clinical Picture—The matter of making a clinical diagnosis of dermatophytosis is usually not difficult. Occasionally, however, chemical dermatitis and skin manifestations of hypersensitivity simulate dermatophytosis. Therefore, because the diagnosis of fungous infection cannot be made with certainty in all cases on clinical grounds alone, the laboratory evidence of the presence of a dermatophyte by

From the Medical Clinic, the School of Medicine, Johns Hopkins University and Hospital, Baltimore, Maryland. Part of the work described in this paper was done under a contract, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and the Johns Hopkins University.

* Instructor in Medicine, Johns Hopkins University School of Medicine; Assistant Visiting Physician Johns Hopkins Hospital.

microscopic examination or by culture is essential in a scientific study of a skin affection where dermatophytosis is suspected

The dermatophytes produce a characteristic sporulating mycelium in culture (Fig 55) but they are present in the skin and the hair

Fig 55 - The dermatophytes I, *Trichophyton mentagrophytes* II, *Trichophyton rubrum* III, *Epidermophyton floccosum* IV, *Candida albicans* V *Microsporum audouinii* VI, *Microsporum felinum*

as continuous or fragmented hyphae. The demonstration of hyphae, by microscopic examination of material from the infected areas, is sufficient to make a diagnosis of dermatophytosis.

Laboratory Examination—The material to be studied must be collected properly. A scalpel should be used to obtain scrapings of skin from lesions on the toes and in the groin. The active edge, not the center, of the lesion should be scraped. It must be remembered that fungous infections heal from the center and if the hyphae are to be found they will be located at the periphery of the lesion. If the lesion is vesicular, the roof of the vesicle should be completely removed with scissors and if the hair is affected an affected hair should be epilated with forceps. The specimen for examination should then be placed upon a slide and covered with 10 per cent sodium hydroxide. Several hours must elapse to allow the sodium hydroxide to clear the specimen before making the microscopic examination.

It is also desirable to culture material from infected areas. Skin scrapings, or the roof of a vesicle or an infected hair should be planted on Sabouraud's dextrose agar and incubated at 30° C. The identification of the fungus by its gross and microscopic cultural characteristics should be attempted only by an experienced mycologist. The isolation and classification of the fungus is an academic nicety and is not essential for the proper treatment of the patient.

Skin Test—It is important to discuss briefly the value of the skin test in diagnosing dermatophytosis. Once the body has become infected by a fungus certain alterations occur which affect the reactivity of the tissues toward subsequent contact with the fungus or the protein of the fungus. This altered reactivity that results from infection is spoken of as "bacterial hypersensitivity," "hypersensitivity of infection," or "tuberculin type hypersensitivity." It is quite possible that an "anaphylactic" type of hypersensitivity to the polysaccharide fraction of the fungus also develops.

There is available on the commercial market a crude extract of the *Trichophyton* species which is suitable for the testing of "hypersensitivity of infection." This extract is known as *trichophytin*. The test is performed by injecting 0.1 cc. of a 1:30 dilution of trichophytin (Lederle) intradermally on the volar surface of the forearm. The test is interpreted forty-eight hours later and if an area of erythema and induration occurs at the site of injection, it is spoken of as being positive. The positive test only indicates that at some time in the immediate or distant past the host has been infected with fungi and is therefore of limited value in making a diagnosis of dermatophytosis. A negative trichophytin test is helpful in ruling out dermatophytosis just as a negative tuberculin test is of assistance in ruling out a tuberculous infection.

Fluorescence Test—The fact that hairs infected by the *Microsporum* dermatophytes fluoresce under filtered ultraviolet radiation is frequently used as an aid in the diagnosis of fungous infection of the scalp in children. Inexpensive units for the production of filtered ultraviolet radiation are available on the commercial market. These units are

commonly referred to as "Wood's lights," being named for their inventor, Dr Robert Wood, Emeritus Professor of Physics at the Johns Hopkins University

Treatment—A compound to be effective in the treatment of dermatophytosis must first possess the power to inhibit the growth of fungi or actually kill the fungi. Secondly, it must be able to penetrate the stratum corneum and come into contact with the fragments of hyphae that are embedded there. Penetration can be abetted by incorporating the compound into vehicles that possess the power of penetration in their own right. Thirdly, the compound should possess an antibacterial effect, because essentially every fungous infection is complicated by secondary bacterial infection and the hypersensitive reaction to this bacterial infection. Fourthly, the compound and the vehicle in which it is placed should be neither irritating nor sensitizing.

As a result of research recently conducted under the auspices of the Office of Scientific Research and Development^{1, 2, 3, 4} there have been developed two preparations which satisfy the above qualifications. These are *propionate-propionic acid ointment** and *undecylenate-undecylenic acid ointment*†. There is little difference in the clinical effectiveness of these two ointments, but the propionate-propionic acid ointment possesses more antibacterial effect in vitro than the undecylenate-undecylenic acid ointment. It is of further importance to point out that by in vitro tests the propionate-propionic acid ointment has more fungistatic activity than full strength Whitfield's ointment and 10 per cent ammoniated mercury ointment and has more antibacterial effect than full strength Whitfield's ointment, 10 per cent ammoniated mercury ointment, 5 per cent sulfathiazole ointment and 0.5 per cent tyrothricin ointment.

The propionate-propionic acid ointment and the undecylenate-undecylenic acid ointment are satisfactory for the treatment of dermatophytosis of the feet, the groin and the smooth skin and either preparation is an improvement over any one method of treatment that has been formerly employed. In this respect the treatment of dermatophytosis has been fairly standardized.

For the treatment of dermatophytosis of the feet, either ointment should be applied over the toes, between the toes and under the toes every night. The following morning the ointment should be removed with soap and water or with a towel and the feet dusted with talcum. A calcium propionate dusting powder‡ is now available which is superior to pure talcum powder. Some of the powder should also be

* Propionate-propionic acid ointment: sodium propionate 16.4, propionic acid 3.6, propylene glycol 5.0, n-propyl alcohol 10.0, "carbowax (4000)" 35.0, zinc stearate 5.0, water sufficient to make 100.0.

† Undecylenate-undecylenic acid ointment: undecylenic acid 10.0, triethanolamine 6.0, propylene glycol 14.0, "carbowax (1500)" 10.0, "carbowax (4000)" 40.0, water sufficient to make 100.0.

‡ Calcium propionate dusting powder: calcium propionate 15.0, talcum 85.0.

dusted into the shoes. This treatment must be adhered to until the lesions have completely healed and then continued for several weeks thereafter. It is important to stress that the use of keratolytic agents, the procedure of opening widely vesicular lesions on the soles of the feet, and the use of warm potassium permanganate (1:3000) soaks for acute eczematoid lesions should not be lost sight of and must supplement the use of either the propionate-propionic acid ointment or the undecylenate-undecylenic acid ointment.

Fig. 56.—Demonstrating the fungistatic effect of 10 per cent sodium caprylate jelly on *Candida albicans* (Agar cup-plate technic of Ruehle and Brewer.) The clear area surrounding the cup represents the zone of complete inhibition.

For the treatment of dermatophytosis of the groin or smooth skin, either ointment should be applied every night and every morning. The ointment should also be applied to the normal skin immediately surrounding the infected area. The treatment must be continued for approximately one week after the lesions have completely healed.

To date the only satisfactory method of treating dermatophytosis of the hairs of the scalp has been *x-ray epilation*. This treatment must be administered by an expert. At the moment there are severe epi-

demics of dermatophytosis of the scalp in New York City, Pittsburgh, Philadelphia and Hagerstown, Maryland Under the auspices of the United States Public Health Service extensive research is being conducted in these communities and it is to be hoped that a satisfactory scheme of medical treatment will be developed as a result of these investigations

The development of the *fatty acids* as inhibitors of pathogenic fungi promises to lend assistance in the treatment of infections due to *Candida albicans* in the mouth (thrush) and in the vagina A 20 per cent solution of sodium caprylate adjusted to pH 7.4 and applied three or four times daily to lesions in the mouth has been very effective A 10 per cent sodium caprylate jelly has been found to be very active in vitro against *Candida albicans* (Fig. 56) and its use in vivo in the treatment of vaginal infections due to this organism appears to be promising

SPOROTRICHOSIS

Sporotrichosis was first discovered in Baltimore by Schenck⁵ in 1896 Four years later Hektoen and Perkins⁶ named the causative fungus, *Sporotrichum schenckii* The great majority of the reported cases have occurred in France, the United States and South America

It is believed that the fungus grows on vegetation and that humans are infected from this source Many cases have followed wounds of the upper extremity by barberry thorns, by straw and by grains Accidental laboratory infections have occurred and there is on record a case in which there was direct transmission from human to human.

Diagnosis—Clinical Picture—The clinical picture of a typical case is so striking that, once seen, the disease will always be readily recognized Extending from the primary lesion, which is usually an ulcer or abscess about the wrist, there will be seen upon the surface of the extremity a line of hard or soft elevated nodules that are neither hot nor tender Between these nodules there are usually reddened lines that demarcate the course of the lymphatic vessels If sufficient time has elapsed between the onset of the disease and the time when the patient first presents himself for treatment, some of the softer nodules will have developed a draining sinus from which pus can be expressed It is rare for the disease to spread beyond the regional lymph glands but Beurmann⁷ of France, has reported cases in which metastatic lesions have occurred in the lungs, the liver and the testicles It is not uncommon to discover that the patient with sporotrichosis is suffering from some debilitating disease which lowers his resistance to infection sufficiently to allow the fungus to gain a foothold One of our cases has diabetes mellitus and there are many cases reported in the literature in which pulmonary tuberculosis has preceded the infection by *Sporotrichum schenckii*

Laboratory Examination—The diagnosis is established by culturing the organism from a subcutaneous abscess A higher percentage of

positive cultures will be obtained if the material to be cultured is aspirated from an abscess that has not as yet opened. It is difficult to identify the organism microscopically from smears of pus.

Fig. 37.—Fungi that produce deep-seated infections. I, *Cryptococcus neoformans*. II, *Sporotrichum schenckii*. III, *Blastomyces dermatitidis*. IV, *Coccidioides immitis*. V, *Phialophora verrucosa*. VI, *Histoplasma capsulatum*.

The character of the growth of *Sporotrichum schenckii* on Sabouraud's dextrose agar is distinctive. At first the colony is whitish, shiny and moist, resembling a bacterial growth. As the age of the culture

increases the whitish color changes to a light tan, then to a coffee brown and finally may become black. The surface of the colony usually remains shiny but becomes wrinkled with age (Fig 57)

Skin Tests—The diagnosis can further be established by skin testing. Moore and Davis⁸ as early as 1918 obtained positive "tuberculin-like" skin tests by injecting intradermally a killed spore suspension. We have recently been able to demonstrate positive skin reactions with 0.1 cc of a 1:1000 dilution of a two weeks old broth filtrate of *Sporotrichum schenckii* (Fig 58). The broth filtrate gives negative reactions in normal controls.

Fig 58—Demonstrating the results of skin tests with 1:1000 dilutions of broth filtrates of *Sporotrichum schenckii* prepared from stock and autogenous species. Numbers 1, 2, 3, 4, 5 and 6 represent results obtained from stock strain filtrates prepared after cultures had grown 1, 2, 3, 4, 5 and 6 weeks, respectively. Numbers 7, 8 and 9 represent results obtained from autogenous strain filtrates prepared after cultures had grown 2, 4 and 6 weeks, respectively. Sufficient antigen was obtained after a growth of 1 to 2 weeks to elicit positive skin reactions. Tests were read after 48 hours.

Treatment—The disease usually responds dramatically to the administration of *iodides*. Just recently we have treated two patients with parenteral injections of *fatty acids*. One patient received intramuscular injections and local applications of sodium undecylenate and the second patient received intravenous injections and local applications of sodium caprylate. Both fatty acid salts are effective *in vitro* against *Sporotrichum schenckii*.⁸ Neither patient improved under intensive treatment but both patients responded readily to the oral administration of potassium iodide (Figs 59 and 60).

Fig 59—Illustrating the effectiveness of potassium iodide in the treatment of sporotrichosis. I and II, Before treatment. III and IV Eight weeks after treatment. Potassium iodide was administered to the point of intolerance which for this patient was 36 gm daily Patient was discharged taking 25 gm. daily

We have not been able to demonstrate by in vitro tests that the sulfonamides or penicillin are sufficiently effective to warrant their use clinically in the treatment of this fungous infection^{9, 10}

Fig 60—Illustrating the effectiveness of potassium iodide in the treatment of sporotrichosis I, Before treatment II, Four weeks after treatment Efficacious results were obtained with small doses of potassium iodide (6 gm daily)

COCCIDIOIDOMYCOSIS

Coccidioidomycosis is the name originated by Dickson^{11 12} of Stanford University for the disease produced by the fungus, *Coccidioides immitis*. The disease was actually first reported in South America in 1892 by Wernicke¹³. It is imperative not to confuse coccidiosis with coccidioidomycosis. Coccidiosis is an infection produced by one of the animal parasites included in the order Coccidia of the class Sporozoa. The Coccidia commonly infect the intestines of chickens and other birds, the livers of rabbits, and the intestines of dogs and cats.

The fungus, *Coccidioides immitis*, occurs in the soil of arid regions of the United States, that is, the San Joaquin Valley in Southern California, Southern Arizona, Southern Utah, Western Texas and a portion of New Mexico, and has also been found in Northern Mexico, Italy and Hawaii. Emmons¹⁴ has recently suggested that the fungus may have a rodent reservoir.

Diagnosis—Initial Infection—Very frequently individuals living in endemic areas may become infected without manifesting any clinical evidence of the disease. Furthermore, the lesions heal and confer upon these individuals immunity against subsequent infection. Individuals moving into or through endemic areas may acquire an initial infection

which manifests itself by signs and symptoms characteristic of many acute respiratory infections. There is usually fever from 99° to 101° F accompanied by malaise, backache, chest pain, cough, headache, chills and night-sweats. The onset of these symptoms may be either abrupt or insidious. A diagnosis of "influenza" is frequently made.

Approximately two weeks after the onset of the initial infection, symptoms and signs of hypersensitivity may occur. About 5 per cent of the patients develop either erythema nodosum or erythema multiforme and a small per cent complain of pains in the joints.

The pulmonary lesions, which roentgenologically resemble tuberculous infiltrations, usually undergo fibrosis and calcify. Occasionally necrosis within the pulmonary lesions will cause the development of a cavity. The cavity usually closes spontaneously, is thin-walled and may be confused with a tuberculous cavity. Interestingly enough the cavity may persist and remain "silent" except for the presence of coccidioides in the sputum and an occasional hemoptysis which appears after exertion. Otherwise the patient is well and resists exogenous and endogenous reinfection.

Progressive Disseminated Infection—The fungus disseminates in only about 0.1 per cent of the patients infected, but when it does the result is fatal. The symptomatology of the progressive disseminated infection depends entirely on the sites to which the fungus has spread. In white patients meningitis is common and the chronic course simulates tuberculous meningitis. Furthermore, tuberculosis is imitated by an occasional miliary spread to the bones and joints, peritoneal cavity, lymph nodes and skin. In the dark skinned races there is more of a tendency to the development of multiple subcutaneous and joint abscesses. The ankle joint particularly for some reason is frequently singled out.

The term "coccidioidal granuloma" which is commonly used in the literature to describe the progressive disseminated type of infection is an unfortunate one and should be abandoned. Actually the residual lesions of the initial infection as well as the lesions of the progressive disseminated infection are known to be granulomatous in their histologic structure. It is better, therefore, to speak of 'initial' and 'disseminated' coccidioidomycosis for these terms connote the pathogenesis of the disease.

Laboratory Diagnosis—*Coccidioides immitis* exhibits marked dimorphism. It grows on agar as a white cottony mold which pigments with age (Fig 57). Old cultures contain myriads of very large, thick-walled spores known as chlamydospores. These spores which are particularly adapted for maintaining vitality through long periods of dormancy are considered to be the infective form of the fungus occurring in nature. When these spores are injected into animals they become spherical and enlarged. These large spherical cells, commonly referred to as 'spherules' give rise to endospores by cleavage of their cytoplasm. The endospores escape when the wall of the 'spherule' ruptures.

and repeat the parasitic phase of the life cycle. It is the "spore" that is found in the sputum of patients infected with *Coccidioides immitis*.

Patients who are infected or have been infected with *Coccidioides immitis* give a positive "tuberculin-like" skin reaction to the intradermal administration of 0.1 cc. of a 1:100 dilution of *coccidioidin*. Furthermore, coccidioidin can be employed as an antigen for precipitation and complement fixation tests. Precipitins are usually present in the initial infections that are clinically apparent but are absent in disseminated infections. The titer of complement fixation usually varies with the severity of the infection.

The sedimentation rate of red corpuscles is accelerated in *coccidioidomycosis*. There is an increase in the leukocyte count after the initial infection with a concomitant eosinophilia. As the infection is arrested a relative and absolute lymphocytosis occurs.

Treatment—There is no specific form of treatment for *coccidioidomycosis*. In vitro and in vivo tests with the sulfonamides have failed with failure. Penicillin likewise is ineffective. The use of thymic extracts has never given satisfactory results. A strict regimen of rest is the best method of effecting a cure. In other words, the patient should be treated as though he had tuberculosis and should remain in bed until he has clinically recovered, until the x-rays have indicated the lesions to be regressing and until the sedimentation rate has returned to normal.

BLASTOMYCOSIS

This disease was first discovered in Baltimore in 1894 by Gilchrist, who later¹⁶ named the causative fungus *Blastomyces dermatitidis*. Actually the name blastomycosis is doubly a misnomer. It was thought that the causative organism was a true yeast and secondly it was thought that "*Blastomyces*" was the proper scientific name for the yeasts. Actually, however, the organism is not a true yeast though it has a yeastlike form in the tissues, and *Saccharomyces* is the proper scientific name for yeasts and not "*Blastomyces*."

Diagnosis—Clinical Picture—In the majority of cases the primary lesion appears on the skin of the face, hands, wrists or forearms. There first appears a firm papule and about this a number of secondary nodules develop which gradually enlarge and coalesce. The lesions break down and discharge purulent material from their centers. As the lesion progresses there appears a large, elevated mass of tissue with an irregular ulcerated surface that resembles somewhat a tuberculous ulcer. Healing occurs first in the central portion of the lesion and is followed by the formation of scar tissue.

The disease tends to progress slowly. Dissemination may occur by spread through the subcutaneous tissues, by contact, and by way of the lymphatics or the blood stream. Any organ or tissue in the

may be attacked. The lungs are frequently involved and the symptoms and signs of pulmonary blastomycosis bear a striking resemblance to those of pulmonary tuberculosis.

Laboratory Diagnosis—The diagnosis is established by demonstrating the organism in pus or sputum. In the body tissues the fungus occurs only as a round or oval yeastlike cell which reproduces by budding. These cells are easier to demonstrate if the material to be examined is first treated with 20 per cent sodium hydroxide. The finding of doubly-contoured budding cells with granular contents and which in size are slightly smaller than leukocytes makes the diagnosis certain.

Cultures are readily obtained on Sabouraud's dextrose agar if there are not too many contaminating bacteria. The colonies first appear smooth and grayish but soon become wrinkled. Finally a white, cottony growth with a central umbo develops (Fig. 57). Cultures on blood dextrose agar incubated at 37° C. do not develop a filamentous growth but remain yeastlike in appearance.

Skin Test—The diagnosis can further be established by skin testing. A tuberculin-like skin reaction is obtained in patients with blastomycosis by injecting intradermally a heat-killed vaccine prepared from the yeastlike form of the fungus.

Treatment—If the patient presents himself in the early stages of the disease when the lesion is small and accessible, the *surgical removal* of the lesion is advisable. If, however, the lesion is not suitable for surgical excision *x-ray therapy* in addition to large doses of *potassium iodide* should be recommended.

If the disease has disseminated, iodides are usually ineffective and actually may be dangerous in patients who have developed a hypersensitivity to the fungous infection. Martin and Smith^{17, 18} have properly recommended desensitization with a heat-killed vaccine before the institution of iodide therapy in patients who are hypersensitive. They believe that satisfactory results can be obtained often from iodide therapy in systemic blastomycosis if desensitization is first carried out.

Recently we have demonstrated^{9, 10} by in vitro studies that the sulfonamides and penicillin are not effective against *Blastomyces dermatitidis* and we feel that their use in the treatment of cutaneous or disseminated blastomycosis is not indicated.

CRYPTOCOCCOSIS (TORULOSIS)

Cryptococcosis was first described in Germany in 1895 by Busse¹⁹ and Buschke.²⁰ The causative fungus, *Cryptococcus neoformans* (*Torula histolytica*), is a yeastlike organism which has a special affinity for the tissues of the central nervous system but which may also attack the lungs as well as other organs of the body. It may also produce a localized infection of the skin.

Diagnosis.—Clinical Picture—As a rule the disease begins insidiously with symptoms pointing to involvement of the central nervous system.

Persistent severe headache, stiffness of the neck and vomiting are common complaints. Later dimness of vision and diplopia may occur. Convulsions are not uncommon. Examination of the spinal fluid usually reveals an increase in pressure with an increase in lymphocytic cells and occasionally there is an increase in the albumin and globulin content. A specific diagnosis cannot be made from these signs and symptoms, and it is not until the yeast cells are demonstrated in the spinal fluid sediment or the organism cultured on Sabouraud's dextrose agar that one can be certain of the diagnosis.

The lungs are frequently affected and the clinical picture is often confused with pulmonary tuberculosis and other pulmonary mycotic infections. The primary lesion is thought to occur in the lungs with metastases occurring to the brain by way of the blood stream. The organism may similarly disseminate to involve other organs of the body, particularly the spleen, liver, kidneys and skin.

Laboratory Examination—The diagnosis is established by demonstrating budding yeast cells in the centrifuged spinal fluid sediment. In a Gram's stain preparation these cells stain dark blue with a reddish capsule.

On Sabouraud's dextrose agar the organism grows slowly. At first the growth is moist, smooth and cream colored. As the culture ages the color changes to yellow and then to brown (Fig. 57).

Treatment—No effective method of specifically treating this fungous infection has been reported. The disease is slowly progressive and usually fatal. The administration of large doses of *potassium iodide* to the point of intolerance is warranted. The organism is not very susceptible to the *sulfonamides*, but sulfathiazole in a concentration of 10 per cent completely inhibits the growth *in vitro*⁹ and because of the lack of specific methods of treatment an intensive course of sulfonamide therapy is justifiable. Penicillin does not inhibit the growth of the organism *in vitro*¹⁰ and its use in the treatment of this disease is not indicated. The treatment for the most part must be purely symptomatic.

CHROMOBLASTOMYCOSIS

The first case of chromoblastomycosis was studied by Pedroso²¹ in Brazil in 1911. Lane²² described the first case in the United States in 1915 and Medlar^{23, 24} in the same year was the first to grow the causative fungus, which was named *Phialophora verrucosa*. The disease, although rare, is worldwide in distribution. Eight cases have now been reported in the United States. It is important to note that many fungi have been described as causing chromoblastomycosis but most of the cases have been due to either *Phialophora verrucosa* or *Hormodendrum pedrosoi*. The name of the disease, chromoblastomycosis, was selected on the basis of the dark color of the fungous cells in the lesions. Then, too, the disease was thought to resemble in many ways blastomycosis. All races are susceptible. The laboring classes, particu-

larly the agriculturists, are almost exclusively affected. This is probably due to their contact with vegetation.

Diagnosis.—The disease is confined to the skin and for the most part the lesions are unilateral and occur on the lower extremities. There is frequently a striking similarity to blastomycosis. The typical lesions which develop over a period of several years are pedunculated cauliflower-like excrescences which occasionally ulcerate. Elephantiasis may develop concomitantly. Regional adenopathy frequently occurs and is thought to be the result of secondary bacterial infection in the primary mycotic lesion. Systemic manifestations to the infection do not occur unless there is a secondary bacterial infection. Local pain and pruritus infrequently occur.

The diagnosis is established by demonstrating brownish, thick-walled, septate cells in the pus removed from fresh lesions. In the old necrotic lesions small septate filaments may be observed.

The organism grows very slowly on Sabouraud's dextrose agar. The colonies appear velvety and vary in color from dark olive to black (Fig. 57).

Treatment.—The disease is slowly progressive but never fatal. If the patient is seen early in the course of the disease the lesion or lesions should be excised. If the disease has progressed so that surgical removal is impossible, x-ray therapy combined with large doses of potassium iodide should be recommended. We have recently demonstrated⁹ that *Phialophora verrucosa* is completely inhibited in vitro by sodium sulfamerazine in a concentration of 50 mg. per cent. Therefore, the use of sodium sulfamerazine or sulfamerazine in the treatment of chromoblastomycosis due to *Phialophora verrucosa* is warranted. Penicillin does not inhibit the growth of *Phialophora verrucosa* in vitro¹⁰ and its use in the treatment of this disease is not indicated.

HISTOPLASMOSIS

The disease, histoplasmosis, was first discovered in the Panama Canal Zone by Darling²⁵ in 1906. Darling originally believed the causative organism was a protozoan and therefore gave it the name *Histoplasma capsulatum* and accordingly named the disease histoplasmosis. De Monbreum²⁶ in 1934 reported that the organism could be grown in yeast-like and mycelial forms. Furthermore, De Monbreum²⁷ produced the disease in monkeys and demonstrated that the intracellular phase of the parasite was the yeastlike form. He firmly established the fungus as the etiologic organism in histoplasmosis. As a result of his studies, De Monbreum proposed to change the name of the fungus and of the disease because of Darling's misconception of the systematic position of the organism but since Darling created a new generic and a new specific name for the parasite such a change is not warranted. The disease is not common and to my knowledge the diagnosis has been made before autopsy in only one reported case.

Diagnosis—Clinical Picture—The picture is usually that of emaciation, weakness, fever, anemia, leukopenia and splenomegaly. Hepatomegaly, ulcerative colitis and lymphadenopathy have been described. Various skin manifestations such as erythema, purpura and urticaria have been observed. It is advisable to consider histoplasmosis in the differential diagnosis of any obscure case of splenomegaly, particularly if the splenomegaly is associated with fever and leukopenia. Furthermore, it is important to examine the stools for fungi in patients with refractive diarrhea and ulcerative colitis, especially if no pathogenic organisms have been isolated.

Laboratory Examination—The fungus in its parasitic phase is a small yeastlike organism ranging in diameter from 2 to 3 microns. These yeastlike bodies resemble closely the Leishman-Donovan bodies of kala-azar and invade the mononuclear cells in enormous numbers. In cases in which the diagnosis of histoplasmosis is suspected the mononuclear cells in the circulating blood and in the bone marrow should be examined carefully under an oil immersion lens for intracellular bodies. If there is enlargement of the lymph glands, a biopsy should be made.

Cultures should be made on Sabouraud's dextrose agar and blood dextrose agar from the blood and the sternal bone marrow. If there is enlargement of the lymph glands a portion of the gland removed for biopsy should be pulverized and cultured. On Sabouraud's dextrose agar the organism produces a white, cottony growth (Fig 57). Spores ranging in size from 10 to 25 microns are produced and from these spores rise finger-like projections, 5 microns in length. The growth on blood dextrose agar is yeastlike.

Treatment—Because the diagnosis of histoplasmosis is rarely made before death, treatment for this fungous infection has not been developed. We have recently demonstrated⁹ by *in vitro* experiments that the growth of *Histoplasma capsulatum* is completely inhibited by *sodium sulfathiazole* in a concentration of 50 mg per cent. Therefore the possible clinical effectiveness of sodium sulfathiazole or sulfathiazole in the treatment of histoplasmosis might be anticipated. Penicillin¹⁰ does not inhibit the growth of *Histoplasma capsulatum* *in vitro* in concentrations that would warrant its use clinically.

ACTINOMYCOSIS

The term actinomycosis does not refer to one specific disease caused by one specific organism. The term does indicate an infection due to an actinomycete. In man there are three well defined types of infection caused by species of actinomycetes. (1) The most common type is caused by *Actinomyces bovis*. This organism is an anaerobic, nonacid-fast, gram-positive actinomycete that is responsible for the cervicofacial, thoracic and abdominal lesions that are so well known to all clinicians. It is also the cause of lumpy jaw in cattle. (2) Another type of infection is caused by *Nocardia asteroides*, an aerobic, acid-fast

staining organism that is frequently the cause of pulmonary and brain lesions (3) The third type of infection is caused by *Actinomyces madurae*. This organism is the etiologic agent in Madura foot, a disease which is endemic in India, particularly in the city of Madura This discussion will be limited to infections produced by *Actinomyces bovis* and *Nocardia asteroides*

Actinomycosis Due to *Actinomyces Bovis*—The mode of infection and transmission has not been firmly established It is commonly taught that the habit of chewing straw leads to infection, but *Actinomyces bovis* has never been isolated from vegetation. On the other hand, the organism is known to be commonly present in and about carious teeth, in dental scum, and in crypts of tonsils, and it is reasonable to assume that the infection disseminates from these areas

Diagnosis—The *clinical manifestations* of infection fall into three categories depending upon the region of the body affected The cervicofacial region is most frequently involved, comprising about 60 per cent of the cases The thoracic and abdominal regions are involved next in frequency and comprise together about 40 per cent of the cases The cervicofacial type is frequently associated with dental defects or accidents and is a chronic infection which usually remains localized and which can be treated successfully In the thoracic and abdominal types the prognosis is poor The primary lesion in the thoracic type is in the lung The actinomycetes are either inhaled directly into the lung or spread by aspiration from a neighboring focus of infection in the mouth The pulmonary lesion may resemble a tuberculous infection but there are definite differences which aid in the differential diagnosis In pulmonary actinomycosis the lower lobes are first involved and there is never a spread to the hilar lymph nodes Cavity formation is rare. The infection spreads by continuity and frequently invades the diaphragm and the chest wall In abdominal actinomycosis the primary lesion is often in the appendix In all cases there are draining sinuses and at autopsy abscesses are frequently found in the liver Meningitis and endocarditis rarely occur Generalized actinomycosis from hematogenous spread has been reported

The diagnosis of actinomycosis is established by finding the organism in the pus in the form of very characteristic "sulfur granules" These granules vary in size, have a radiating lobulated structure and are usually yellow in color They are best observed with the low-power microscope lens Occasionally they are large enough to be identified with the naked eye or with a hand lens The interior of the granule does not stand out sharply, but the clubs at the periphery are very refractile and appear as irregular lines marking the borders of the lobules By crushing the granules between two slides and then staining with Gram's stain the gram-positive branched filaments can be demonstrated These branched filaments make up the interior of the "sulfur granule"

The organism is difficult to culture Pus should be washed with sterile normal salt solution Granules should be recovered with a bacteriological loop, washed again in sterile normal salt solution and then placed in thioglycollate media and incubated at 37° C The inoculated tube should be retained for four weeks before discarding Colonies appear as fluffy masses of mycelium

Treatment—Treatment for the most part is unsatisfactory and consists of indicated *surgical drainage*, the administration of *potassium iodide* to the point of intolerance and *x-ray therapy* There are numerous clinical notes in the literature proclaiming the effectiveness of the *sulfonamides*, particularly sulfanilamide,^{28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38} sulfapyridine,^{34, 39, 40} and sulfadiazine^{38, 41} In the majority of these reported cases surgical measures, iodide and x-ray therapy supported the sulfonamide therapy and it is impossible to ascribe the entire clinical improvement to the action of the sulfonamides The reported results on the use of *penicillin*^{42, 43, 44} are no more impressive than the results reported for other therapeutic measures It must be concluded that necessary surgical intervention, adequate x-ray therapy and intensive iodide administration are essential adjuncts to either sulfonamide or penicillin therapy if optimal results are to be obtained in the treatment of this chronic infection

Actinomycosis Due to Nocardia Asteroides—In approximately 10 per cent of the cases of clinical actinomycosis the causative organism is the aerobic, acid-fast actinomycete, *Nocardia asteroides* Throughout the English and American literature the term "streptotrichosis" is frequently used to describe the clinical manifestations produced by *Nocardia asteroides* The term is confusing and should be abandoned

Diagnosis—*Nocardia asteroides* commonly infects the lungs and quite frequently disseminates by way of the blood stream to the brain The clinical manifestations of pulmonary actinomycosis due to *Nocardia asteroides* are identical to those due to *Actinomyces bovis* Because *Nocardia asteroides* fails to produce granules and because it is acid-fast there may be difficulty in differentiating it from the tubercle bacillus In contrast to the tubercle bacillus, treatment with sodium hydroxide kills the acid-fast actinomycetes This fact is of practical importance in differentiating actinomycosis due to an acid-fast actinomycete and tuberculosis, because guinea pigs fail to develop lesions following the injection of sputum containing acid-fast actinomycetes which has been treated with sodium hydroxide Fresh sputum injected into guinea pigs will produce lesions from which can be recovered the branching acid-fast organisms typical of *Nocardia asteroides* Drake and Henrici⁴⁵ have recently demonstrated that a specific hypersensitivity develops following an infection with *Nocardia asteroides* which can be demonstrated by skin testing with the protein fraction of the organism The skin test, therefore, is of further assistance in the differential diagnosis

Treatment—The treatment for actinomycosis due to *Nocardia asteroides* is identical to that for actinomycosis due to *Actinomyces bovis*. In other words, there is no specific treatment. Sulfonamides or penicillin used concomitantly with iodide and x-ray therapy and necessary surgical drainage will produce optimal clinical results.

THE DIAGNOSIS AND TREATMENT OF BRUCELLOSIS

WESLEY W. SPINK, M.D., F.A.C.P.*
AND WENDELL H. HALL, M.D.†

TOWARD the end of the last century, a young army surgeon was attached to the British forces on the Island of Malta. While there, his wife, two sisters and himself contracted brucellosis. Returning to England to convalesce, Hughes wrote and published a monograph in 1897, now considered a classic, on "Mediterranean, Malta or Undulant Fever." The introductory sentence of the preface states, "When the writer arrived in Malta towards the end of the year 1890, for a six years tour of service in that place, he found that his medical work would chiefly consist, during the greater part of the year, of treating a fever about which no two medical officers appeared to agree, respecting its cause, treatment or even name." Almost fifty years have elapsed since the foregoing statement was made, and in the intervening time the cause of brucellosis has been definitely established, but physicians are still perplexed by diagnostic and therapeutic problems relating to this disease. This confusion is not due to a lack of interest in the subject. Many investigations, both experimental and clinical, have been made, several important reports have appeared, including two informative monographs,^{1, 2} but still the question is asked, how may one establish an unequivocal diagnosis of brucellosis? And if an accurate diagnosis is established what therapeutic procedure shall one carry out for a patient with the disease?

The purpose of this clinic is to summarize briefly the outstanding features of the disease, to evaluate the diagnostic procedures now available, and to present today's therapy. For information we have drawn largely from our clinical experience with this disease at the University of Minnesota Hospitals during the last seven years, and from the documented observations of other investigators.

ETIOLOGY AND MODES OF TRANSMISSION

As will be pointed out shortly, the accurate diagnosis of brucellosis often calls for a correlation of many factors including certain epidemiologic data. Microorganisms belonging to the genus *Brucella* are responsible for the disease. They are small, motile or nonmotile, gram-

negative rods with many coccoid forms. At the present time, three species are recognized, *Brucella abortus* (cattle), *Brucella suis* (swine) and *Brucella melitensis* (goat). It is not unlikely that these three species have had a common origin, and that specific biological or metabolic characteristics for each species have arisen as a result of adaptation to different hosts. It is important that these differences in species should be kept in mind by the clinician since they are frequently reflected in the severity of the disease and also in the results of therapy. While cattle, swine and goats constitute the large reservoir for *Brucella*, other animals are known to be naturally infected. These include sheep, horses, mules, deer, buffaloes, dogs, rabbits and poultry.³ Nevertheless, cattle, swine and goats constitute the main sources of disease for human beings. It is generally agreed that *Brucella suis* is more invasive for human tissue than *Brucella abortus*. It should be borne in mind that each of the species may reside in hosts other than that for which it is named. Thus, an epidemic of human disease due to *Brucella suis* has arisen from the ingestion of raw cow's milk.⁴ Horses have been shown to be infected with *Brucella abortus*, and cases of human infection have been traced to this source.^{5, 6}

The disease is transmitted to human beings via the gastrointestinal tract and through the skin. One of the most common sources of infection is the ingestion of contaminated milk or milk products. Although this mode of transmission undoubtedly results in many infections, it is surprising how difficult it is to establish the disease both in human subjects and in lower animals by the experimental feeding of large doses of viable *Brucella*.⁷ This probably accounts for the many instances of subclinical infections with the development of hypersensitivity to *Brucella* antigen. The second common method of transmission is by direct contact with contaminated or infected material with entrance of the bacteria through the skin. It has been demonstrated experimentally that guinea pigs may be infected by applying cultures to the normal or abraded skin.⁸ Human beings have been experimentally infected in a similar manner through abraded skin but not through the intact skin.⁷ Although human beings may excrete viable *Brucella* in the feces or urine for long periods of time, no authentic human to human infection has been recorded. Nevertheless, soiled bed linen may possibly serve as a basis for a hand to mouth infection. *Brucella* organisms have been recovered from the milk of a nursing mother,⁹ but have been isolated from the sputum very rarely. While biting flies and mosquitoes have been shown to transmit the disease experimentally, no natural spread has been traced to this source.³ Another possible route of infection is through the respiratory tract following the inhalation of dust containing *Brucella*. Microorganisms may remain viable in shaded dust or soil for one to two months.¹⁰ Monkeys have been experimentally infected following the inhalation of dust containing *Brucella melitensis*.¹¹ It is also of importance that *Brucella* organisms

have been found to be viable after two months in Roquefort cheese, four months in refrigerated butter, and ten days in refrigerated milk. *Brucella suis* has withstood refrigeration in hogs' spleens for thirty days at -10° degrees F., and in meat-curing brine for forty-five days.¹⁰

An analysis of thirty-five cases of brucellosis seen at the University of Minnesota Hospitals shows that probably all were due to *Brucella abortus*. This is associated with the fact that twenty-two, or 63 per cent, of the patients consumed raw milk obtained from infected cattle, and seven patients, or 20 per cent, handled infected material from aborting cattle. With the exception of one packing plant employee, the source of the infection could be traced.

CLINICAL MANIFESTATIONS OF BRUCELLOSIS

The usual procedure in discussing the clinical features of brucellosis is to divide the analysis into a consideration of the acute and chronic phases of the disease. This division is sound provided one does it in relation to the time factor, that is, acute brucellosis should indicate a symptom complex of short duration, whereas chronic brucellosis should imply the presence of symptoms for a period of several weeks or months, and in a few instances, for years. An explanation of an obvious and well recognized classification of disease is given because, too often, chronic brucellosis is described as an ill-defined entity with few or no localizing signs. Most of the errors and difficulties in diagnosis relate to the chronic cases, and the diagnosis is frequently made upon the basis of inadequate clinical and laboratory data. As will be described shortly, cases of chronic brucellosis may exhibit many of the clinical manifestations usually associated with the acute stage of disease. In addition, the chronic cases may have important localized signs of the infection.

Acute Brucellosis—The incubation period varies from five to twenty-one days with an average of ten to fourteen days. The common signs and symptoms together with the relative frequency have been excellently summarized by Hardy and his associates¹¹ based on an analysis of 300 case studies in Iowa. A review of a smaller group of cases at the University of Minnesota Hospitals was in agreement with these observations.¹² The onset of clinical brucellosis may be sudden or insidious. Clinical symptoms resembling acute respiratory infections are not uncommon, and diagnoses such as "la grippe," 'influenza,' or 'intestinal flu' are often made. The *febrile response* may be marked and may be sustained as in typhoid fever, or intermittent, as in pyogenic infections. In milder cases, a low-grade fever may be present. The *pulse rate* is often relatively slow in proportion to the fever. The outstanding complaint in all cases is *weakness*, which in the mild cases may be the only subjective complaint. *Sweating*, moderate to profuse, is experienced by a majority of individuals who contract the disease. *Chilliness*, often a symptom observed during the period of invasion

frequently persists and frank chills may usher in the daily rise of temperature seen in the more severe cases *Pain* usually takes the form of a generalized malaise and tends to persist in the ambulatory patient, and to be aggravated by physical exertion. The pain, when it is localized, is generally manifested by headache, arthralgia, lumbar pain, or abdominal pain. The latter may be prominent and has in more than one instance led to an erroneous surgical diagnosis. Simpson¹⁴ has information on twelve appendectomies and two cholecystectomies carried out in patients with brucellosis, resulting in normal pathological specimens. *Gastrointestinal disturbances* usually take the form of anorexia and constipation. Diarrhea is rare. *Painful swelling of the testicles* is apparently not infrequent, though we have not recognized a single instance in our series. Of the exhibited *neurologic disorders*, insomnia, restlessness and irritability are most common, while delirium and coma are rare.

Subclinical Infections—It is becoming more and more apparent that there are many individuals whose tissues are invaded by *Brucella*, but the infections are so mild that they escape detection. Furthermore, symptoms may be entirely absent, and yet tissue sensitivity to the microorganisms has been induced, and serologic tests will reflect such an invasion. There are several reports of subclinical infections occurring in epidemics of brucellosis involving individuals who have ingested contaminated milk.^{15, 16, 17, 18, 19} These mild or subclinical infections are more likely to occur following invasion with *Brucella abortus*. In this respect brucellosis is like tuberculosis. It is this group of patients who present a difficult problem in differential diagnosis at a late period when they present themselves to a physician with ill-defined symptoms and possess immunological evidence of brucellosis. It is important to bear in mind that the subclinical type or ambulant case of brucellosis may have a demonstrable bacteremia.²⁰

Chronic Brucellosis—Chronic brucellosis may be the sequela of an acute, febrile illness, which may or may not have been recognized as brucellosis initially, or the disease may have had an insidious onset originally, and the ill-defined symptoms have persisted over a long period of time. As Evans^{21, 22} has pointed out, many of the patients with chronic brucellosis have been diagnosed as having neurasthenia. The outstanding clinical features are a multiplicity of physical and mental complaints with few or no localizing signs. The most common complaint is *weakness*. The patients tire readily. A low-grade fever may be present, usually intermittently. There are *vague aches and pains* referable to the skeletal system and muscles. Low back pain is frequently present. *Mental depression* occurs, as well as *nervousness and emotional instability*. *Tachycardia, palpitation* and *sweats* appear following exertion. Physical examination may reveal splenomegaly and hypotension in a small group of cases. Little wonder then that chronic brucellosis is confused with neurasthenia or "constitutional inade-

quacy" On the other hand, patients with neurasthenia or psychoneurosis are more often labeled as having chronic brucellosis on the basis of the symptomatology and inconclusive laboratory data The difficulties encountered in making an unreserved diagnosis of chronic brucellosis will be discussed subsequently in relation to the laboratory aids in diagnosis.

PATHOLOGY OF BRUCELLOSIS

The histopathology of brucellosis has not been clearly defined Forbus²³ has recently summarized the information at hand as follows He described three fatal forms of the disease, namely, the septicemic or relatively acute form, the focal or localized form of infection, which is also relatively acute, and the chronic lymphogranulomatous type. There are no distinguishing features in the septicemic type. The localized forms include vegetative endocarditis, meningitis, orchitis and osseous lesions The lymphogranulomatous form demonstrates what Forbus believes to be characteristic lesions for brucellosis The basic reaction involves the reticulo-endothelial system with a proliferation of large mononuclear cells This is succeeded by necrosis and then a proliferation of fibroblasts or a scar composed of reticulum Multinucleated giant cells are seen which closely resemble the Sternberg or Dorothy Reed cells of Hodgkin's disease In fact, Parsons and Poston⁴ described the lesions in a fatal case of granulomatous brucellosis as being indistinguishable from those found in Hodgkin's disease. This excited the interest of the Duke University investigators, and in a subsequent report²⁵ they recorded the isolation of *Brucella melitensis* from the blood or lymph nodes in fourteen consecutive cases of Hodgkin's disease, whereas in a control series of sixty-seven cultures of lymph nodes obtained from individuals without Hodgkin's disease, only one yielded *Brucella*²⁶ While the Duke workers have implied a possible etiologic relationship between Hodgkin's disease and brucellosis, much more confirmatory evidence from other centers is desirable concerning the incidence of brucellosis in patients having Hodgkin's disease.

In two fatal cases of brucella endocarditis due to *Brucella abortus* studied at the University of Minnesota Hospitals,^{27 28} granulomatous lesions of the reticulo-endothelial system were not observed, but in several organs a mononuclear type of cellular reaction was noted

LOCALIZING SIGNS OF BRUCELLOSIS

The following brief discussion emphasizes the protean manifestations of brucellosis, and may be of aid in recognizing the disease.

Ocular Manifestations.—It is becoming more and more apparent that diseases of the eye of obscure origin may be related to brucellosis Chronic uveitis is one of these conditions^{29 31} Brucellosis may involve the internal ocular muscles, the cornea, the uveal tract, the retina and

the optic nerve Therefore, errors in vision which at first would not appear to be due to an infection may be attributable to this disease

Oral Manifestations—*Brucella* organisms have been recovered from the ulcerated lesions of the mucous membrane of the mouth and the oral pharynx³² Some individuals recommend a careful culture of the tonsils and oral pharynx in every person suspected of having brucellosis This does not appear to be unreasonable since brucellosis is a disease which involves the reticulo-endothelial system, and invasion of the tissues is frequently through the oral pharynx

Pulmonary Manifestations—Patients with brucellosis, not infrequently, may have a persistent cough An atypical form of pneumonia may occur *Brucella melitensis* has been isolated from sputum³³ and from empyema fluid³⁴ A review of the literature on the pulmonary changes in brucellosis has been reported by Bogart³⁵ We have encountered a fatal case of brucella endocarditis, in which pneumonia was present, and the outstanding histologic feature was an exudate consisting almost entirely of mononuclear cells We have also seen one patient with a pleural effusion in association with brucellosis

Vegetative Endocarditis—This appears to be a relatively uncommon manifestation of brucellosis, and yet we have encountered two fatal cases at the University Hospitals in seven years^{27, 28} One of the important diagnostic features is that the patients may have a high titer of agglutinins in the blood, a bacteremia, and yet the intradermal injection of *Brucella* antigen may provoke no local reaction An analogous phenomenon is observed in patients having vegetative endocarditis due to streptococci of the viridans type Whenever a patient has the manifestations of bacterial vegetative endocarditis, and routine bacteriological procedures have failed to reveal the etiologic microorganisms, investigations should be directed toward excluding *Brucella* as the possible cause In this manner, our two cases of brucella endocarditis were resolved

Biliary Tract—Brucellosis may involve the biliary tract *Brucella* have been isolated from the bile and gallbladder in patients with cholecystitis³⁶ and have been implicated as a cause of hepatitis³⁷ Since *Brucella* have an affinity for the reticulo-endothelial system, it is not surprising that hepatitis may be observed It is not unlikely that cirrhosis of the liver may also occur We have seen a few instances of portal cirrhosis in patients in whom a presumptive diagnosis of brucellosis had been made on the basis of immunologic reactions Although we have cultured the bile of several patients having brucellosis with bacteremia, we have not isolated the organisms from the bile Zaus and Espev³⁸ are of the opinion that patients having a previously damaged liver are more likely to show further evidence of hepatic damage from brucellosis

Manifestations Referable to the Male and Female Genitalia, and Relation of Brucellosis to Human Abortions—A commonly reported manifes-

tation of brucellosis in males is orchitis resulting in swelling of the testicles. However, this has not been observed in our series at the University Hospitals. Pelvic inflammations in females, particularly tubo-ovarian abscesses, have also been reported. Again, no proven case has been encountered at the University Hospitals.

While brucellosis in pregnant lower animals is frequently associated with spontaneous abortion, the incidence of undoubted cases in human beings is rare. Carpenter and Boak³⁹ have reviewed the literature on the subject, and report the isolation of *Brucella abortus* from a human fetus, and French workers⁴⁰ have isolated *Brucella melitensis* from the tissues of a fetus and the blood of a mother. While some authorities in this country⁴¹ believe that miscarriages occur with frequency in women having chronic brucellosis, more precise bacteriologic data are needed. It would be highly desirable for some of the larger centers, particularly those in endemic areas, to institute studies of all instances of unexplained human miscarriages in an attempt to establish the incidence of such an association. We have not observed a single proven case of this type at the University Hospitals.

Lymphadenopathy.—Reference has already been made to the observation that enlargement of the superficial lymph nodes occurs in brucellosis; that *Brucella* may be cultured from lymph nodes, and that the histology of the nodes in some instances is not unlike that seen in Hodgkin's disease. An analysis of the literature by Bloomfield⁴² would indicate that lymphadenopathy is not an uncommon manifestation of brucellosis. In a series of thirty-five cases at the University Hospitals, nine of the patients, or 25.7 per cent, had enlarged peripheral lymph nodes. Attention has recently been called to the clinical similarity between some cases of infectious mononucleosis and brucellosis.⁴³ In both diseases, lymphadenopathy may be a prominent feature.

Splenomegaly.—When present, a palpable spleen constitutes a very helpful manifestation of brucellosis. In our own series of thirty-five proven cases, the spleen was palpated at some time during the course of their illness in fourteen of the patients, or in 40 per cent. The spleen is more likely to be palpable during the acute phase of the disease.

Skin Lesions.—Various types of dermatologic lesions have been described as occurring during the course of brucellosis.² In general, these consist of macular lesions, maculopapular lesions, localized and generalized erythema, purpura, lesions simulating erythema nodosum, lesions indistinguishable from the "rose spots" of typhoid fever, and ulcerating and eczematous lesions. We have observed one patient with acute brucellosis and bacteriemia who had a butterfly type of erythematous lesion over the bridge of the nose and cheeks, not unlike that seen in acute disseminated lupus erythematosus. Huddleson¹ has recorded two types of skin lesions as occurring in veterinarians. One consists of an erythema of the arm, which appears after the manual removal of placentae from aborting cows, and is associated with itching or

burning but no desquamation or exudation. This type is considered to be due to a hypersensitivity to a placental protein. The second type is due to a specific allergy resulting from a *Brucella* infection, and it displays discrete, elevated, reddish lesions, which burn and itch, and later ulcerate. Systemic reactions may accompany the skin lesions. The lesions may last for three to four weeks.

The following case illustrates an acute *Brucella* infection with a pronounced skin eruption, in which the illness terminated rapidly.

CASE I—A 28 year old white man, an insurance agent, was in good health until four days before entry to the University Hospitals. The onset of his illness was marked by a chill which lasted thirty minutes. There was no preceding upper respiratory infection. On the following day he continued to have chilly sensations with generalized stiffness of the muscles. Two days after the onset, a rash appeared on the skin of his upper and lower extremities without itching or tenderness. He then developed a cough productive of mucoid, frothy material. There was no chest pain. On the day of entry he had a chill lasting one hour. He perspired profusely and complained of slight rigidity of the neck. About two weeks prior to his illness he drank some water from a questionable source. There was no history of tick bites.

Examination revealed a febrile patient appearing acutely ill. He was perspiring profusely. The sclerae were injected. The pharynx appeared normal. The heart and lungs were within normal limits. The abdomen was slightly distended. A tender and soft spleen was palpated about 3 cm below the right costal margin. The skin over the arms, legs and abdomen was involved with a slightly elevated, discrete, pink eruption. The lesions were of different sizes and faded on pressure. Similar lesions were present on the soles of the feet, around the ankles, a few on the back, but none on the palms of the hands. The superficial lymph nodes were not enlarged.

On the day after entry the patient complained of pain in the joints of the right ankle and right wrist. He was acutely ill. An intradermal test with vaccine prepared from *Brucella abortus* showed a slightly positive reaction at the end of forty-eight hours. The initial leukocyte count was 3300 cells, with a differential count of 60 per cent polymorphonuclear neutrophils and 40 per cent lymphocytes. The leukopenia persisted throughout his illness. An erythrocyte sedimentation rate was within normal limits. His blood cultures remained sterile. Agglutinins for *Brucella*, *B. typhosus*, and *B. tularensis* were absent on the second and fifth hospital days, but on the ninth day, a titer of 1 to 1280 for *Brucella abortus* was obtained, no agglutinins for other pathogens were present. Guinea pigs injected with the patient's blood shortly after entry failed to show evidence of an infection, and when sacrificed, *Brucella* were not cultured from any of the organs.

Forty-eight hours after entry to the hospital the patient was given sulfanilamide in doses of 1 gm every six hours, after an initial dose of 4 gm. He received a total of 18 gm in five days. Coincident with this therapy his condition improved rapidly, and the skin eruption faded. He left the hospital nine days after entry. This patient was seen at intervals during the following five years. There has been no recurrence of his illness, and his blood has failed to show the presence of agglutinins for *Brucella*.

Nervous System—De Jong⁴⁴ has reviewed the literature pertaining to the involvement of the nervous system in brucellosis. Headache is a common manifestation. Peripheral neuritis may occur, which may persist for weeks. Unexplained instances of peripheral neuritis should oc-

casion an investigation for the possibility of brucellosis. Invasion of the central nervous system may produce encephalitis, meningitis and myelitis. *Brucella* have been isolated from the cerebrospinal fluid.

Joint Manifestations.—Pain referred to the joints is a common manifestation of brucellosis. While the tissues surrounding the joints may be swollen, reddened and tender, and an effusion may be present, brucellosis rarely, if ever, causes a chronic arthritis.⁴⁵ Intermittent hydrarthrosis, particularly of the knee joint, has been reported, and *Brucella* organisms have been isolated from the synovial fluid.

Spondylitis.—A common manifestation of both acute and chronic brucellosis is pain over the spine, involving especially the lumbosacral areas. In many instances the precise nature of this pain is difficult to ascertain, but careful roentgenologic studies of the site of pain should be made in order to exclude the possibility of spondylitis. The lesion begins in the marrow of the vertebra and the intervertebral disks are involved secondarily. The lesion of brucellosis must be distinguished from a tuberculous process, and osteomyelitis due to pyogenic bacteria. The condition has been reviewed by Bishop,⁴⁶ and Feldman and Olson⁴⁷ have described specific spondylitis in swine due to *Brucella*. These lesions were discovered only after careful dissection and occurred in apparently healthy animals.

We have recently reviewed the literature on spondylitis due to *Brucella*, and we have found sixty-eight cases recorded. At the University Hospitals, we have studied five patients with *brucella* spondylitis.

The following case demonstrates the chronicity of brucellosis and the late development of spondylitis in a patient who had a bacteremia. At first, the patient was considered to have a tuberculous lesion of the spine for reasons to be detailed.

CASE II.—A 25 year old white male employed as a shipping clerk entered the University Hospitals because of fever, generalized muscular pain, night sweats and lumbar pain radiating into both thighs. He had been drinking raw milk, but there was no demonstrable evidence of Bang's disease in the cattle from whom the milk was obtained. The patient's mother and brother had both died of tuberculosis in his home. His illness began about eleven months before entry when he developed weakness, anorexia and a failure to maintain his normal weight. Four months later he developed the symptoms which prompted his entry to the University Hospitals.

On entry the patient appeared well developed, fairly well nourished, and chronically ill. His temperature was 99.6 F. There was no lymphadenopathy. The lungs were clear and there were no cardiac abnormalities. The liver and spleen were not palpable. There was tenderness upon percussion over the spinal processes of the second, third and fourth lumbar vertebrae. There was spasm of all the lumbar muscles, and the lumbar spine was held rigid.

The leukocyte count was 8100 cells, with 66 per cent polymorphonuclear neutrophils, 33 per cent lymphocytes and 1 per cent monocytes. The sedimentation rate of the erythrocytes was markedly accelerated. The Wassermann test was negative. The calcium, phosphorus and phosphatase values of the blood were normal. Agglutinins were present in his serum for *Brucella abortus* in a titer of

1 to 2580, and an intradermal test with *Brucella* vaccine provoked a marked reaction. The Mantoux test was strongly positive. Blood cultures for *Brucella* taken at the time of his admission remained sterile. However, it was learned that his physician had submitted a specimen of blood to the laboratories of the Minnesota State Board of Health seven months previously and *Brucella abortus* was found to be present.

Roentgenologic examination of the lungs was normal, but films of the lumbar region revealed considerable destruction of the intervertebral disk between the second and third lumbar vertebrae and destruction of the bodies of these two vertebrae. There was some enlargement of the shadow of the left psoas muscle suggesting the possibility of a psoas abscess. There was also an area of rarefaction in the right sacroiliac joint suggestive of a destructive form of arthritis.

An attempt to aspirate material for cultural purposes from the left psoas region was unsuccessful. The patient was given sulfanilamide in an initial dose of 4 gm and then 1 gm every six hours. He received a total of 56 gm in seven days. This maintained a blood level of 10 mg per 100 cc. Coincident with this therapy, his temperature gradually approached normal. A plaster-of-paris body jacket was applied, which afforded complete relief of his back pain. He left the hospital in a body cast forty-five days after entry.

Three months later the patient returned to the hospital. He had no fever or back pain and had gained 20 pounds in weight. There was slight tenderness upon percussion over the third lumbar spinous process. The leukocyte count was 5900 and the erythrocyte sedimentation rate was normal. Roentgenologic examination of the lumbar spine showed increased destruction of the intervertebral disk between the second and third lumbar vertebrae, but there was less decalcification of bone. A Taylor body brace was applied, and he was permitted to return to work eleven months after his first entry to the hospital. Soon thereafter he discarded the brace and he has been doing heavy work without having back pain. There has been no remission of his illness in a period of three years.

LABORATORY AIDS IN THE DIAGNOSIS OF BRUCELLOSIS

As pointed out by Foshay,⁴⁸ clinicians are leaning too heavily upon laboratory procedures for making a correct diagnosis of brucellosis. In a consideration of each suspected case it is necessary to bear in mind the epidemiology of the disease, the many manifestations of brucellosis, and then correlate them with the various laboratory data. As part of the investigations on brucellosis which we have been carrying out in our clinic, Miss Suzanne Agnew⁴⁹ performed a number of laboratory procedures in eighty-five cases suspected of being brucellosis. There were forty-nine control patients. These procedures were carried out simultaneously and included the following: complete hematologic studies including hemoglobin determinations, erythrocyte levels, total leukocyte and differential counts. Agglutination titers were determined simultaneously by the "rapid" slide method of Huddleson and the multiple tube or macroscopic method. The complement fixation test was evaluated. Opsonocytophagic indices were performed according to the method of Huddleson,⁵⁰ and with a second test suggested by Jersild.⁵¹ Two different media for culturing *Brucella*: blood were investigated. Intradermal tests were performed with a heat-killed vaccine, with "brucellergin," and with a purified protein derivative of *Brucella*.

The following discussion is based largely upon the results of the foregoing study and the investigations of others

Blood Leukocytes.—In several instances, our attention has been called to the possibility of a febrile patient having brucellosis because of the presence of a lymphocytosis in the peripheral blood. While it is often assumed that a leukopenia is present, this is by no means the rule. The total leukocyte count may be normal, below normal or actually elevated. We have encountered levels of 15 000 cells per cubic millimeter. The important factor is the presence of a relative or absolute rise in the lymphocytes. This diagnostic feature has been excellently presented by Calder and his associates.⁶² We are of the opinion that the erythrocyte levels or hemoglobin concentrations are not of particular value.

Sedimentation Rate of Erythrocytes.—Brucellosis is one of the few infectious diseases in which the sedimentation rate may remain normal throughout the course of the disease. This factor may constitute additional evidence favoring a diagnosis of brucellosis.

Agglutinins.—Clinicians rely considerably upon the presence of agglutinins in the blood serum for making a diagnosis of brucellosis and rightly so. The test is of value when used in conjunction with the clinical findings and other laboratory data. There are several points to consider in evaluating the results of the test. First, an appreciable number of patients with active brucellosis may not have agglutinins in the blood even in the presence of suppurative lesions. This may be related to the invading strain of *Brucella*, which may be a poor antigen, or may be due to the failure of the patient to respond. Castaneda and his associates⁶³ observed that about 10 per cent of their patients with bacteremia had no agglutinins. Second, it may take several days or weeks after the onset of an acute illness before agglutinins may be detected. Third, the titer may fluctuate from time to time, agglutinins being absent on some occasions. Fourth, the antigen used for the agglutination test is of some importance. Thus, one laboratory may report the presence of agglutinins in a specimen of blood while another laboratory may not, each using a portion of the same serum for the test.

The question is frequently asked as to what titer of agglutinins is diagnostically significant as far as active disease is concerned. One cannot give an arbitrary titer as being diagnostic in itself. In general, the higher the titer, the more likely is the clinician to demonstrate a bacteremia. This has been our experience and that of others.⁶⁴ Repeated tests should be done in a patient suspected of having the disease.

It is well recognized that agglutinins will appear in the blood in normal subjects following the intradermal injection of *Brucella* antigen. This response is usually in evidence during the second or third week after the test. Usually titers less than 1 to 100 are obtained. At least, that has been our observation as well as that of Kirby and Rantz.⁶⁵ This applies to patients having a negative or positive dermal reaction. On the other hand, Menefee and Poston⁶⁶ observed that positive dermal reactors may have a considerable elevation of the agglutinin titer especially during the third week after the injection. We do not believe that the titer of the agglutinins following an intradermal test with antigen is of diagnostic significance as to whether or not the patient has an active disease process.

It is of significance that in an individual whose tissues have been invaded by *Brucella*, with or without clinical evidence of the disease, agglutinins may persist in the blood for months or years. Under these circumstances a nonspecific rise in the titer of the agglutinins may shortly follow an unrelated febrile illness, such as streptococcal sore throat.¹⁶ It is this type of phenomenon which lends confusion to the diagnosis of chronic brucellosis.

In summary then, the agglutination test is a valuable diagnostic aid in brucellosis only when correlated with other laboratory data, the clinical illness, and

epidemiologic factors In performing the test, the "rapid" slide agglutination of Huddleson may be used, or the macroscopic tube method Neither test is of any advantage over the other, though we prefer to carry out the latter test

Complement Fixation Test—This test has been thoroughly investigated in our clinic and it does not appear to possess any advantage over the agglutination test except that complement-fixing antibodies appear earlier in the blood than agglutinins in some instances This is in accord with the opinion of others⁵⁷ Because additional information obtained from the results of the complement fixation reaction is so slight, its routine use is not advocated

Opsonocytophagic Test—Much has been written about this diagnostic procedure, still it is surprising what little clinical information may be obtained from its use This applies to its application in the diagnosis of an active infection, and also its use in ascertaining the immune status of the patient A similar conclusion was reached by Wise⁵⁸ The test has been completely evaluated in our clinic by Agnew,⁴⁹ and the conclusion reached is that the test is of little aid in itself, but may contribute to the diagnosis when used in conjunction with other procedures The standard test requires the use of virulent microorganisms, and there exists a potential danger in its routine use as far as laboratory personnel is concerned There is recent evidence that the test may be performed with killed organisms At present, the opsonocytophagic test is not being used in our clinic

Skin Test—This is the most abused diagnostic procedure and provides the clinician with the least reliable information A positive cutaneous reaction following the intradermal injection of *Brucella* antigen should be interpreted in the same light as the tuberculin reaction A positive test does not necessarily imply an active infection or even a past clinical infection It reflects a state of hypersensitiveness to *Brucella* antigen in individuals who have had contact with the material at some time in the past As pointed out already, patients may actually have a bacteremia with a *brucella* endocarditis and yet no dermal reaction may be provoked following the injection of the antigen Material widely used in skin testing individuals includes a heat-killed vaccine and brucellergin which is a nucleoprotein fraction of the cells Heat-killed vaccine usually containing cells from the three species of *Brucella* provokes violent local and systemic reactions at times We prefer brucellergin since the reactions are milder In the last two years we have been using the purified protein antigen prepared by Dr Morales Otero⁶⁰ of San Juan, Puerto Rico and supplied to us through his courtesy This material produces fewer local and systemic reactions than does the vaccine.

It should be emphasized that in clinical practice the skin test is of little diagnostic aid in itself This has been our experience and has been beautifully shown by the excellent investigations of Heathman,⁶⁰ which involved several hundred workers in the larger packing plants of Minnesota The intradermal injection of any *Brucella* antigen may sensitize some normal individuals to the antigen, and may be followed by the development of agglutinins This may be confusing when a patient is seen subsequently by different physicians

Again, the skin test should only be used in conjunction with other procedures, and interpreted with relation to the clinical status of the patient

Blood Culture—Specimens of venous blood should be obtained from every patient suspected of having brucellosis and the blood should be added to an appropriate culture medium It is our policy to culture blood every other day for at least three times, particularly in suspected acute causes In chronic cases, cultures of blood may be carried out at less frequent intervals A variety of culture media have been proposed for the isolation of *Brucella* including liver infusion broth During the past few years, the Laboratories of the Minnesota State Department of Health have been handling the blood cultures for the University Hospitals, and the procedure has been highly satisfactory The medium with 1 per cent sodium citrate Twenty

five cubic centimeters of broth are contained in large vaccine bottles. To each bottle is added 5 cc of blood directly from the patient. Utilizing sterile precautions, 10 per cent of the air in the bottle is replaced by carbon dioxide. This is done because the growth of the species *Brucella abortus* is facilitated by the increased carbon dioxide tension. After incubation for five days at 37° C., subcultures are made upon several dextrose agar slopes, and the tubes incubated further in a jar containing added carbon dioxide. Usually, at the end of forty eight hours, colonies of *Brucella* may be seen on the agar slants. Occasionally strains of *Brucella abortus* grow very slowly and a longer period of observation may be necessary. Identification of the *Brucella* as a group is made by fermentation tests and by employing a potent antibrucella serum for the agglutination reaction. The species may be differentiated by the dye method of Huddleson.¹

In the foregoing manner *Brucella* have been isolated from the blood of acutely febrile patients, and also from the blood of patients who have been chronically ill and afebrile. When a bacteremia has been demonstrated bacteriologically there is no doubt about the diagnosis. During the past seven years, we have cultured the blood repeatedly in well over 100 patients strongly suspected of having brucellosis, and *Brucella*, all of the *abortus* variety have been isolated from only ten individuals. During this time, thirty five patients have been considered as having the active form of the disease. This means that bacteremia was demonstrated as being present in a little less than one third of the patients.

Brucella may also be obtained from human sources other than from the blood. The organisms have been isolated from bile and stools, as well as from urine.⁶¹ Some investigators routinely culture the tonsils in suspected cases, since *Brucella* organisms have been isolated in this manner.⁶²

In summary, the practical laboratory aids which we have found applicable to suspected cases of brucellosis are the blood leukocyte and differential counts, the erythrocyte sedimentation rate, and the macroscopic agglutination reaction and cultural studies, particularly repeated cultures of blood. The skin test with appropriate antigen is the least helpful. Other laboratory procedures such as the complement fixation reaction and opsonocytophagic test can only be carried out in certain centers and are not enough of an aid to the clinician to warrant their routine use.

BRUCELLOSIS IN CHILDHOOD

It is generally assumed that infants and young children are relatively resistant to *Brucella*. It is well known that it is difficult to establish a well-defined disease in calves and kids with *Brucella*. Certainly, the established incidence of brucellosis in children is less than that encountered in adults. Whether this age distribution means that the disease is generally unrecognized in children, or that young children are resistant to the disease, is difficult to assay. Experience at the University of Minnesota Hospitals would indicate a low incidence of active disease in young children, and when the infection does occur it is usually mild and the disease goes unrecognized. This coincides with the experience of others.²⁰

Over a period of seven years, several hundred individuals including children, have been investigated for the presence of brucellosis, and the disease was definitely established as being present in only two

children under twelve years of age. The essential clinical features in one of these children are as follows:

CASE III—A 6 year old white male was seen with Dr. Ralph Platou on the Pediatric Service. The child had always enjoyed good health until approximately four months before entry when he developed chickenpox. Following this he continued to complain of marked fatigue, and he became more and more listless. He had a daily temperature elevation of 102° to 104° F. About three weeks before admission he was seen by Dr. Platou who suspected brucellosis because of a palpable spleen as the only localizing physical abnormality. Blood sent to the Laboratories of the Minnesota State Department of Health revealed agglutinins for *Brucella abortus* present in a titer of 1 to 640, and a pure culture of *Brucella abortus* was isolated from his blood. He was given sulfadiazine over a period of ten days in doses which established a blood level of free sulfadiazine of 11.5 mg per 100 cc.

Because improvement was slow, it was decided to admit the patient to the hospital, continue with sulfadiazine therapy, and, in addition, institute treatment with artificial fever by means of a cabinet. On entry his temperature was 101.6° F. There was moderate cervical and axillary adenopathy and the tip of the spleen was palpable. The hemoglobin was 11 gm., leukocytes 4300 per cubic millimeter, with 20 per cent polymorphonuclear neutrophils, 69 per cent lymphocytes, 2 per cent monocytes, 8 per cent eosinophils and 1 per cent basophils. A blood culture failed to reveal the presence of *Brucella*. During the first eleven days the patient received sulfadiazine, with a blood level of free sulfadiazine being maintained between 15.6 and 18.8 mg per 100 cc. He developed a maculopapular skin eruption and leukopenia and neutropenia, which abated when treatment with sulfadiazine was omitted. In addition, he was given four treatments with artificially induced fever at 105° F for four hours. He recovered completely, and left the hospital fourteen days after entry.

It was learned that this child ingested raw milk obtained from a local dairy. One other case of brucellosis was traced to this source.

TREATMENT OF BRUCELOSIS

There are two major factors which must be taken into consideration in evaluating any specific agent for the treatment of brucellosis, as pointed out so well by Carpenter and Boak.⁶³ First, brucellosis is a disease having spontaneous remissions no matter what treatment is prescribed. The course of the initial febrile attack may last for a few days up to several weeks. As we have emphasized, brucellosis at times may be a very mild disease, particularly in those infections due to *Brucella abortus*. It is known that rest in bed will alleviate the symptoms and the temperature will drop to normal, although the bacteremia may persist. The average duration of an attack of brucellosis is about three months.⁶³ A second factor, important in the interpretation of therapeutic results, is related to the accuracy of the diagnosis. A review of the literature would indicate that in many instances there exists some doubt concerning the correct diagnosis. With the foregoing facts in mind, we have attempted to evaluate the results of specific therapy for brucellosis.

Chemotherapy.—Various chemotherapeutic agents have been tried in brucellosis and include methylene blue, mercurochrome, acriflavine,

methyl violet, metaphen, neoarsphenamine, neosalvarsan and, more recently, atabrine. There is no satisfactory evidence that these compounds are of specific value.

Of late, much interest has been attached to the therapeutic effectiveness of the *sulfonamides*. Here again, confusion exists because these compounds have been used in some patients where there is every right to question the diagnosis of brucellosis. There appears to be little doubt that all the more commonly used sulfonamides inhibit the *in vitro* growth of the three species of *Brucella*, and also offer some degree of protection, at least, to experimentally infected animals.^{64 65 66, 67} We have observed *in vitro* that sulfadiazine will readily inhibit the growth of *Brucella* in therapeutic concentrations of the drug. This is particularly applicable to strains of *Brucella abortus*, which are more meticulous in their growth requirements than *suis* or *melitensis* strains.

We are convinced from our own experience that the sulfonamides are effective in the treatment of human infections, although Urschel⁶⁸ in a review of the literature in English expresses some doubt about sulfonamide therapy. But if one excludes most of the chronic cases treated, and centers attention on those instances where the disease has been proved to exist beyond any reason for doubt, one is impressed by the value of the sulfonamides. We have the impression that the sulfonamides are most effective in acute infections due to *Brucella abortus*, and in those patients who have a good immune response as reflected in the agglutinin titer. We agree with the majority of clinicians that the sulfonamides are of little or no value in the chronic ambulatory patient not having a demonstrable bacteremia. Although we have experienced satisfactory therapeutic results in patients having chronic brucellosis, the individuals selected for treatment were febrile, showing evidence of an active disease process being present. We cannot escape the conclusion that failure with the sulfonamides in chronic cases may be due to a mistaken diagnosis or the use of inadequate doses over too short a period. We have not treated a single ambulatory patient with sulfonamide. In the cases selected, the patients have been febrile, and have required hospital and bed care as a part of their treatment. As far as could be determined, all the patients were suffering from infections due to *Brucella abortus*. Wise⁶⁹ has indicated that sulfonamide therapy in adequate doses will not eradicate a bacteremia due to *Brucella suis*. We have some confirmatory evidence for this observation in that a patient with an acute brucellosis due to the *suis* species improved considerably during a course of sulfonamide treatment but the bacteremia persisted during the immediate afebrile, convalescent period.

At the University Hospitals, the sulfonamides have been administered to eight of ten patients having a bacteremia due to *Brucella abortus*. Of the group of eight patients, five had the chronic form of the

children under twelve years of age The essential clinical features in one of these children are as follows

CASE III—A 6 year old white male was seen with Dr Ralph Platou on the Pediatric Service The child had always enjoyed good health until approximately four months before entry when he developed chickenpox Following this he continued to complain of marked fatigue, and he became more and more listless He had a daily temperature elevation of 102° to 104° F About three weeks before admission he was seen by Dr Platou who suspected brucellosis because of a palpable spleen as the only localizing physical abnormality Blood sent to the Laboratories of the Minnesota State Department of Health revealed agglutinins for *Brucella abortus* present in a titer of 1 to 640, and a pure culture of *Brucella abortus* was isolated from his blood He was given sulfadiazine over a period of ten days in doses which established a blood level of free sulfadiazine of 11.5 mg per 100 cc

We are convinced from our own experience that the sulfonamides are effective in the treatment of human infections, although Urschel⁶⁸ in a review of the literature in English expresses some doubt about sulfonamide therapy. But if one excludes most of the chronic cases treated, and centers attention on those instances where the disease has been proved to exist beyond any reason for doubt, one is impressed by the value of the sulfonamides. We have the impression that the sulfonamides are most effective in acute infections due to *Brucella abortus*, and in those patients who have a good immune response as reflected in the agglutinin titer. We agree with the majority of clinicians that the sulfonamides are of little or no value in the chronic ambulatory patient not having a demonstrable bacteremia. Although we have experienced satisfactory therapeutic results in patients having chronic brucellosis, the individuals selected for treatment were febrile, showing evidence of an active disease process being present. We cannot escape the conclusion that failure with the sulfonamides in chronic cases may be due to a mistaken diagnosis or the use of inadequate doses over too short a period. We have not treated a single ambulatory patient with sulfonamide. In the cases selected, the patients have been febrile, and have required hospital and bed care as a part of their treatment. As far as could be determined, all the patients were suffering from infections due to *Brucella abortus*. Wise⁶⁹ has indicated that sulfonamide therapy in adequate doses will not eradicate a bacteremia due to *Brucella suis*. We have some confirmatory evidence for this observation in that a patient with an acute brucellosis due to the *suis* species improved considerably during a course of sulfonamide treatment but the bacteremia persisted during the immediate afebrile, convalescent period.

At the University Hospitals, the sulfonamides have been administered to eight of ten patients having a bacteremia due to *Brucella abortus*. Of the group of eight patients, five had the chronic form of the

disease, and three the acute form. One patient with endocarditis due to *Brucella* failed to respond to either sulfanilamide or sulfathiazole. Of the remaining seven patients, it was necessary to discontinue sulfonamide therapy in two individuals because of toxic reactions, and artificial fever therapy was instituted. Both of these patients recovered completely and have remained in good health. Of the other five patients, one had a temporary relapse following sulfonamide therapy, but recovered completely after a second course of sulfonamide treatment. With the exception of this one patient, all have remained in good health for one or more years following treatment. *The bacteriemia was eradicated in every instance coincident with the use of a sulfonamide except in the patient with brucella endocarditis.*

Eighteen patients without a demonstrable bacteriemia, but for whom it is believed satisfactory evidence was at hand to establish the disease, were treated with the sulfonamides. There were five acutely ill patients, and all recovered completely and have remained well for more than a year. Of the thirteen patients with the chronic form of the disease, nine have had a complete remission of symptoms for one or more years. There were four who failed to respond satisfactorily. One of these four patients was unable to tolerate sulfonamide treatment, and recovered following artificial fever therapy. A second patient was given two courses of sulfonamide therapy without improvement, and then received artificial fever therapy with but slight temporary improvement. A third patient had a good temporary response, but then relapsed. A fourth was given a short course with a sulfonamide, and then artificial fever therapy with a satisfactory recovery.

In the initial attempts to evaluate sulfonamide therapy, sulfanilamide, sulfapyridine or sulfathiazole was employed. During the last two years we have used sulfadiazine and, more recently, sulfamerazine. It is our policy to hospitalize patients for treatment, and continue therapy for two to three weeks. Blood concentrations of sulfadiazine or sulfamerazine are maintained around 10 mg per 100 cc. Four grams of sulfadiazine are given as an initial dose, and then one gram every four to six hours. Each adult patient is given 4 gm of soda bicarbonate four times a day in order to insure an alkaline urine. Fluids are administered so that the daily urinary output is from 1000 to 1500 cc. With sulfamerazine, slightly smaller doses are given and at less frequent intervals.

There is no reason to believe that penicillin will prove effective in the routine treatment of patients having brucellosis. Preliminary in vitro studies indicate that strains of *Brucella* are quite resistant to the action of penicillin.

Vaccine Therapy—For the most part, *Brucella* vaccine has been reserved for the treatment of chronic cases of brucellosis. There is no unanimity of opinion that such a vaccine is specific for brucellosis. Carpenter and Boak⁶³ conclude that a specific effect is lacking and favorable results are due to nonspecific systemic reactions. Evidence

in favor of this view is that satisfactory results have followed the intravenous injection of killed typhoid-paratyphoid organisms⁷⁰ Harris² is a firm advocate of the employment of heat-killed *Brucella* vaccine. There is also a difference of opinion as to whether a clinician should use a mixed *Brucella* vaccine, or the vaccine obtained from a single species of *Brucella*. Furthermore, some advocate the intramuscular route of injection, others the intradermal administration, and others warn against its administration by the intravenous route.

Apparently there is some confusion as to how the specific action of *Brucella* vaccine operates. Some maintain that immunity is established as reflected in the opsonocytophagic test. Others feel that the important feature is desensitization of the patient to the products of the *Brucella*. It would appear that both phenomena are present, that is an increase in the antibody response, and an increase in the tolerance of the patient to the vaccine. In interpreting these factors it should be mentioned that immunologists have expressed considerable doubt as to whether any vaccine has a specific therapeutic value in any chronic infectious disease.

As a result of observation in our own clinic, we are not too optimistic concerning the therapeutic value of *Brucella* vaccine. We do not advocate its use in the acute stages of the disease, and in the undoubted chronic case we first prefer a therapeutic trial with the sulfonamides. Failing in this, our second choice is artificial fever therapy which will be discussed shortly. Where *Brucella* vaccine has been used, we have employed a heat-killed vaccine prepared from *Brucella abortus*. The vaccine is given every five days intramuscularly in increasing doses for five or six times, though in several instances we have continued treatment much longer than this. The object is to provoke a moderate systemic reaction with each injection. The dose of the initial injection depends upon the sensitivity of the individual to the vaccine as measured by an intradermal test.

Brucellin—Huddleson and his associates¹ have advocated the intramuscular use of a broth filtrate prepared from the three species of *Brucella*. According to these workers, the immunologic basis for using brucellin is a state of sensitivity of the patient to the material, its injection produces "a systemic allergic reaction which in turn is accompanied by a neutrophilic leucocytosis and increase in immune opsonins." Furthermore, brucellin does not affect the course of the disease in a patient who is not sensitive. We have had no experience with brucellin but we would not consider brucellin the agent of first choice in an acutely ill patient having bacteremia, even though he was sensitive to the material. It is difficult to state whether brucellin is superior to vaccine in the treatment of chronic brucellosis.

Immune Serum—The use of specific antisera prepared from immunizing animals has not been accompanied by very encouraging results.⁶³ Human immune serum appears to be of some value.^{71, 72} We

have not had the opportunity of utilizing any antibrucella serum. Further evaluation of a concentrated antibrucella serum should be encouraged. There is evidence that, in cattle recovering from *Brucella abortus* infection, bactericidins may be demonstrated in the serum in the absence of an appreciable titer of agglutinins.⁷³

Fever Therapy—Physically induced hyperpyrexia has been advocated by Prickman and his associates^{74, 75} in the treatment of selected groups of patients with brucellosis. They advise such therapy for patients with the acute form of the disease, and individuals having bone lesions, such as spondylitis. We have treated five patients having chronic brucellosis in the Kettering hypertherm at the University Hospitals after failure with sulfonamide therapy. Satisfactory results were obtained in four of the five patients. This type of therapy merits further consideration.

SUMMARY AND CONCLUSIONS

Brucellosis is a disease with protean clinical manifestations. The acute stage of the disease may be so mild that it may be overlooked, or the more serious infections may be incorrectly diagnosed. The accurate diagnosis of chronic brucellosis constitutes a major problem in clinical medicine. A precise diagnosis depends upon a correlation of epidemiologic data, that is, a history of exposure to the organisms, certain localizing physical signs, and a careful interpretation of laboratory data. A reliance upon inadequate laboratory findings is often the cause of incorrect diagnoses. For practical purposes, the most dependable laboratory data include a relative or absolute lymphocytosis in the peripheral blood, the presence of agglutinins for *Brucella*, and the isolation of *Brucella* from the tissues or body fluids. The intradermal test with *Brucella* antigen is often more confusing than helpful. When other clinical and laboratory evidence for the disease is present, the skin test may be of aid. A more satisfactory therapeutic agent is needed for brucellosis. At the University Hospitals, the sulfonamides have proved to be definitely beneficial in the therapy of acute and active chronic infections due to *Brucella abortus*. The therapeutic results with *Brucella* vaccine must be carefully interpreted. This also applies to brucellin. The use of potent antiserum should be encouraged and evaluated further. Physically induced hyperpyrexia may be beneficial in selected patients.

CIRRHOSIS OF THE LIVER WITH PARTICULAR REFERENCE TO CORRELATION OF COMPOSITE LIVER FUNCTION STUDIES WITH LIVER BIOPSY

FREDERICK W. HOFFBAUER, M.S., M.D.*; GERALD T. EVANS, M.D.,
PH.D.†, AND CECIL J. WATSON, M.D., PH.D., F.A.C.P.‡

IN MANY instances cirrhosis of the liver presents no great problem in differential diagnosis but often enough its manifestations are perplexing, and it is in this group that the clinician needs all available aids in the solution of the problem. A study of hepatic disease in general resolves itself into two main divisions: (1) recognition of hepatic disturbances when outspoken clinical signs are lacking and (2) recognition of the cause or type of hepatic disease when clinical signs such as jaundice are evident.

THE COMPOSITE LIVER FUNCTION STUDY

The large number of procedures which have been proposed to evaluate the functional status of the liver clearly indicates that no single procedure is in itself entirely reliable or diagnostic. It would probably be unduly optimistic to anticipate a subsequent development of any single method which would regularly reveal the composite functional status of the liver. The innumerable functions of this organ and the variable way that they may be impaired would appear to preclude the possibility of a "miracle" test. The clinician must therefore choose from the array of tests available those best suited to a given case. Thus in the presence of jaundice, the bromsulfalein test has relatively little value, while it is often of the greatest help in seeking for evidence of liver disease in the nonjaundiced subject. Certain tests, such as Hanger's cephalin-cholesterol flocculation, are actually not methods of measuring liver function, but rather, of liver cell injury or irritation.

For the past several years we have been interested in correlating composite studies of liver function with the histology of the liver. In the discussion which ensues, only cases of proven histologic diagnosis

From the Department of Medicine and the Laboratory Service, University of Minnesota Hospital, Minneapolis, Minnesota. Aided by grants from Hormel Research Foundation and the Research Fund of the Graduate School, University of Minnesota. Presented in part before the annual meeting of the Central Society for Clinical Research, Chicago, Nov. 3 and 4, 1944.

Assistant Professor of Medicine, Department of Medicine, University of Minnesota Medical School.

†Associate Professor of Medicine, Department of Medicine, University of Minnesota Medical School. Director of the Hospital Laboratory Service, University of Minnesota Hospitals, Minneapolis, Minnesota.

‡Professor of Medicine, Department of Medicine, University of Minnesota Medical School.

are included. This has depended in part upon needle biopsy, as described in the following, and in part upon necropsy material. For purposes of comparison and easier evaluation in the present study the results of a number of procedures have been recorded graphically in the form of a liver function "profile" or composite record which has been referred to in previous communications^{1, 2}

In the nonjaundiced subject, the following procedures have been included: quantitative serum bilirubin, hippuric acid synthesis, fractional serum protein, cephalin-cholesterol flocculation test, bromsulfalein excretion test, and the quantitative urine urobilinogen test. In the jaundiced patient, this same group of tests, with the exception of the bromsulfalein, is employed. In addition, the serum cholesterol and alkaline phosphatase, the prothrombin time before and after vitamin K administration, and the feces urobilinogen are determined when jaundice is present.

In the majority of these tests, the technics used are those in common practice in clinical laboratories. A few modifications of certain procedures have proved of value. For the quantitative determination of the serum bilirubin a slight modification³ of Malloy and Evelyn's method⁴ has been used. After the addition of the van den Bergh reagent, readings are taken at one minute and again at fifteen minutes representing the prompt direct and the delayed direct reacting bilirubins respectively. The total and the indirect reacting bilirubins are then determined in the usual way. Characteristic values for a case of obstructive jaundice would be recorded as follows: serum bilirubin in milligrams per 100 cc. $1' = 20$, $15' = 23$, total = 28.

In the determination of the ability of the liver to conjugate hippuric acid after sodium benzoate, the intravenous method of Quick⁵ has been employed. In the presence of renal insufficiency hippuric acid excretion is delayed. Machella, Helm and Chornock⁶ have shown that the outcome of the test is in a measure dependent upon adequate urine flow. To evaluate the renal function simultaneously we have simply injected 1 cc of phenolsulfonphthalein (6 mg phenolsulfonphthalein dye) through the same needle after giving the sodium benzoate. The urine specimen is collected at the end of sixty minutes and an aliquot is used to determine the dye excretion, the balance being employed for the determination of the hippuric acid. An excretion of less than 35 per cent of the phenolsulfonphthalein dye in the one-hour sample casts doubt on the reliability of a low hippuric acid excretion as a measure of hepatic cell function. Conjugation may have occurred in the liver but the excretion of the resultant product is retarded by poor renal function. This simple procedure evaluates renal function at the time that such knowledge is most desirable, viz., during the actual hour the hippuric acid test is being conducted.

The urinary and fecal excretion of urobilinogen has been determined by the quantitative method previously described by Watson.⁷

For the cephalin cholesterol flocculation test of Hanger⁸ a commercial antigen* has been found to be satisfactory

The serum alkaline phosphatase has been determined by the procedure described by King and Armstrong⁹ The values are expressed in terms of King-Armstrong units in the figures accompanying the following case reports

The method of Quick¹⁰ has been employed for the prothrombin time determination In the event of an elevated initial value, the determination has been repeated twenty-four hours after the parenteral administration of 1 mg of synthetic vitamin K. The second value has been termed "prothrombin response" on the graphic record form (see Fig 62) The value of such a procedure as an aid in the differential diagnosis of jaundice has been pointed to by Allen and Julian,¹¹ Lord and Andrus,¹² Olwin¹³ and Kark and Souter¹⁴

The use of a composite liver function study, with the results depicted in graphic form, has proved of considerable help in the analysis of hepatic disorders In the charts that accompany the cases cited, the values departing above the midhorizontal line indicate in general a diminishing liver function, while those departing below the line indicate either normal liver function or, in some instances, simple biliary obstruction without disturbance of function. By connecting the various values plotted, one may obtain a 'profile' of liver function for any given case. Eventually it is hoped that the accumulation of sufficient data of this type correlated with the histologic appearance of the liver will then permit diagnostic deductions from the future graphic forms alone.

NEEDLE BIOPSY OF THE LIVER

Since 1942 needle biopsy of the liver has been attempted in eighty-five cases of hepatic disease occurring on the Medical Service of the University of Minnesota Hospitals. The method has often permitted accurate diagnosis in instances where laboratory and clinical findings were inconclusive.

Aspiration of the liver to obtain material for histologic study is not a new procedure. So far as can be determined it was first employed by Lucatello,¹⁵ who however, did not employ fixation or staining, so that the examination of the tissue obtained permitted little in the way of an accurate diagnosis Twelve years after this initial report, Schupfer recorded his observations on aspiration biopsy of the liver¹⁶ He employed modern methods of tissue fixation and staining One of the most extensive series of needle biopsies of the liver was that reported by Bingel¹⁷ in 1923 This account records the use of the method in 100 cases Most of the same cases appear to be included again in a subsequent series of 140 cases reported by Oliver¹⁸ in 1926 Two fatalities due to hemorrhage and one due to peritonitis are listed in this series.

Difco Company Detroit, Michigan.

The earlier reports of aspiration liver biopsy are reviewed in Frola's monograph published in 1935¹⁹ This investigator analyzed sixty-six of his own cases in which liver tissue was obtained by means of suction applied to a small (0.5 mm) bore needle inserted into the liver The material obtained, if one may judge from Frola's published photomicrographs, consisted only of fragments of liver tissue and blood cells The use of a fine-bore needle, while undoubtedly somewhat safer, yields so little tissue that its value is very limited

A most important advance in the use of liver biopsy arose from the studies of two Danish investigators, Iverson and Roholm²⁰ Their method consisted of an aspiration technic through a posterior-lateral approach to the liver, the site of entrance being the ninth intercostal space in the right posterior axillary line Infiltration of a local anesthetic agent is made at this site and the skin punctured with a knife A needle 18 cm long and 2 mm in width is inserted through the pleura and diaphragm and carried into the liver The pointed obturator is then removed from the needle leaving the serrated cutting edge of the needle embedded in the posterior liver surface Suction is applied by means of a Record syringe attached to the needle hub as the needle is advanced several centimeters into the liver This usually results in removal of a small plug of tissue which is drawn up into the needle along with a few cubic centimeters of blood In England, Dible, McMichael and Sherlock²¹ describe satisfactory results with the method of Iverson and Roholm in studies of cases of epidemic, postarsphenamine and homologous serum jaundice as well as in cirrhosis A few untoward results were encountered by this group as well as by the originators of the method These were in the main hemorrhage, the statement is made that the method should be reserved for cases justifying the slight risk entailed

Baron, in 1939,²² reported forty-eight aspiration biopsies of the liver by an anterior approach, entering the liver below the rib margin A 13-gauge needle 9 cm long was inserted into the liver and material was then obtained by suction A fatal hemorrhage occurred in one of the cases in Baron's series The anterior approach was also employed by Chiray, Fiessinger and Roux in a report of forty-one cases published in 1941²³ These investigators recommended a trocar 6 cm in length and 1.5 mm in width After local infiltration anesthesia, the trocar was passed through the anterior abdominal wall beneath the costal margin and into the liver for a distance of 2 cm Suction was then applied and the needle advanced for a depth of another 1 cm Failure to secure tissue was reported in nine instances No untoward result occurred in this series because, as the authors believe, the penetration to a depth of only 3 cm avoids the large vessels of the liver They recommend that the procedure be reserved for enlarged and easily palpable livers, on the basis of our experience, using a similar method of approach to the liver, we concur entirely with this recommendation

Needle biopsy of the liver using the Vim-Silverman needle was described by Tripoli and Fader in 1941²⁴ This needle* (Fig 61) is an ingenious device primarily intended for tumor biopsy²⁵ By inserting this needle into the liver anteriorly beneath the right costal margin Tripoli and Fader obtained satisfactory tissue specimens in a series of cases Local anesthesia was employed, the site of insertion of the needle being at the lateral edge of the right rectus muscle, below the costal margin

In the present series of cases we have employed the Vim-Silverman needle in all instances in which liver biopsy has been done. The pro-

Fig 61—The upper three pieces depict the ordinary Vim-Silverman biopsy needle (MacGregor Instrument Co) The lower set represents a longer needle based on the same principle which has been devised by us to obtain needle biopsy of the liver during peritoneoscopy

cedure is carried out at the bedside except when done at the time of peritoneoscopy When necessary, a preliminary injection of morphine is given to the patient to allay apprehension. The right upper quadrant of the abdomen is prepared with an antiseptic solution and the area draped Procaine solution is infiltrated at the site selected for the needle insertion Infiltration is carried down to the parietal peritoneal surface If some of the anesthetic agent can be injected just at the peritoneum, the procedure is made relatively painless. The infiltrating needle, a 3-inch 22-gauge one, is finally advanced beyond the peritoneum and into the liver Entrance into the liver is noted by movement of the

* MacGregor Instrument Co., Needham, Mass.

needle coincident with respiration. Suction is applied briefly to be certain one has not encountered an abscess or an excessively vascular area. This having been ascertained to satisfaction, the small bore needle is withdrawn. A small skin incision, 3 mm in length, is then made to facilitate passage of the Vim-Silverman needle. The latter is directed through the anesthetized tract and inserted a short distance into the liver substance. The obturator is then withdrawn and the inner-split needle is inserted into the outer one. The inner needle is then advanced its full length so that the two halves of the needle trap a core of liver tissue. Next the outer needle is advanced, moving over the inner-split needle so that the two halves are compressed. In this manner the piece of tissue is secured between the two prongs. One rotation of the outer needle, holding the inner one stationary, serves to cut the tissue core at its base. The two needles are then withdrawn together. The specimen will vary in length from 1 to 2.5 cm. It is about 0.8 mm in width. Fixation of the plug in 5 cc of 10 per cent formalin for twelve to twenty-four hours is recommended.

Following such a procedure the patient may experience mild right upper quadrant discomfort for a few hours. We have limited the use of this method to hospital patients and require twenty-four hours of strict bed rest following the biopsy. It should be emphasized that the procedure is not without slight risk and that it should be reserved for cases in which the liver is definitely enlarged and the lower margin readily palpable at least 5 cm below the costal margin in the right midclavicular line. This limitation of course reduces the applicability of the method but also greatly reduces the risk. In the past two years sixty-five such biopsy attempts have been carried out at the bedside. In fifty instances, a piece of tissue sufficient for histologic examination has been obtained. Nine of the failures occurred in the first twenty attempts, before familiarity with the method had been gained.

Serious hemorrhage from the liver itself has not occurred. In one instance the needle was inserted too deeply into a thin left lobe and passing completely through it, undoubtedly damaged a large vessel beneath. An alarming intraperitoneal hemorrhage resulted, operation was performed as soon as the patient's condition was improved by transfusions. After the blood was evacuated from the peritoneal cavity, the surgeon found a large hematoma at the site of the damaged vessel. The area was left undisturbed and the abdomen was closed. The patient made a surprisingly uneventful recovery and exhibited no apparent after-effect. This case undoubtedly should not have been chosen since the liver was only very slightly enlarged, the left lobe being more easily palpable. Since this one misfortune we have made it a rule never to consider the procedure except in instances in which the liver is definitely enlarged.

The risk of bleeding from the liver surface itself is not great if the needle is prevented from making a linear tear in the parenchyma. The

danger of such a tear is one disadvantage of the methods requiring intercostal insertion of the biopsy needle. With the needle fixed between the ribs, movement of the liver coincident with respiration might result in a laceration of the capsule and parenchyma. This possibility has been commented upon by Baron.²² We have watched the bleeding from the liver as a result of the biopsy with the Vim-Silverman needle when this has been done during laparotomy in the operating room. Not more than 5 to 10 cc of blood has been noted to escape before coagulation occurred. As a routine precaution, the bleeding time, clotting time and prothrombin time of each patient subjected to needle biopsy have been determined. The presence of any serious bleeding tendency is a contraindication. Likewise the presence of passive congestion of the liver or the presence of suspected hepatic abscesses or suppurative cholangitis is deemed a contraindication to needle biopsy. When the need for liver biopsy in the patient with a small or a normal sized liver has arisen, the procedure of peritoneoscopy has been the method of choice.

PERITONEOSCOPY IN THE DIFFERENTIAL DIAGNOSIS OF HEPATIC CIRRHOSIS

The advantages of peritoneoscopy for the diagnosis and study of disorders of the liver have been well described by Ruddock²⁶ and by Benedict.²⁷ This is a procedure that is best carried out in an operating room, although local anesthesia is quite adequate. The visualization of the liver afforded by the method often permits the diagnosis of hepatic cirrhosis. The Ruddock peritoneoscope is equipped with a forcep attachment intended for biopsy.

Biopsy of the liver when taken just beneath the capsule by means of these forceps, has one disadvantage, i.e. that of gaining a false concept of the amount of change throughout the liver, because of increased connective tissue or round cells just beneath the capsule. For this reason we have performed needle biopsy at the time of peritoneoscopy in twenty cases. The Vim-Silverman needle is not long enough to reach the liver surface through the anterior abdominal wall in the presence of the pneumoperitoneum necessary for peritoneoscopy. We have therefore simply increased the length of the needle to 18 cm as shown in Figure 61. This needle is inserted through a separately anesthetized area in the anterior abdominal wall below the right costal margin. With the liver in view through the peritoneoscope the operator can guide the needle into a desired site in the liver. This permits sampling of the liver to a greater depth than is possible by the forcep biopsy method.

ILLUSTRATIVE CASES

The following cases serve to emphasize some of the factors discussed in the preceding pages. In each the question of hepatic cirrhosis entered into the differential diagnosis at some point. The cases serve to illustrate the variable manner in which these different procedures have

aided in arriving at a correct diagnosis. There is no intention to imply that laboratory tests alone make a diagnosis for the clinician. When considered together with the history and the physical examination they do, however, permit an increased accuracy of diagnosis in hepatic disease. The addition of liver biopsy aids still further in the solution of some of the problems encountered.

CASE I—J S, a housewife aged 54 years, was referred to the hospital with the diagnosis of carcinoma of the pancreas and resultant common bile duct obstruction. Jaundice had been present for ten months, it was painless in its onset. Abdominal distention had been gradually increasing for four months prior to hospital entry. The patient complained of pruritus of moderate severity. During the period of jaundice the stools were light in color and the urine dark. Review of the patient's past history revealed little of note. She had had an episode of jaundice as a child, during an epidemic of infectious jaundice. No residual ill effects could be recalled.

Physical examination revealed a well nourished white woman. The degree of jaundice was marked, the skin exhibited a greenish yellow cast. Over the shoulders and upper chest, numerous "spider nevi" were present, of the type commonly seen in cases of hepatic cirrhosis. The abdomen was distended and free fluid was readily demonstrated. Edema of the ankles was present. Following diuresis induced by a mercurial, the decrease in ascites permitted palpation of a large firm liver extending 15 cm below the costal margin.

The results of the composite liver function study are depicted graphically in Figure 62. The degree of hyperbilirubinemia (Fig 62, SB) was marked. Of considerable interest was the complete exclusion of bile from the intestinal tract as evidenced by the practical absence of urobilinogen from the feces (Fig 62, FU). This was confirmed by repeated stool examinations. A value of feces urobilinogen below 5 mg per day is seen commonly in jaundice due to cancerous obstruction and infrequently in jaundice due to cirrhosis.²⁸ The lack of increase of the urine urobilinogen in this case (Fig 62, UU) does not necessarily reflect inadequate liver function. In the presence of complete biliary obstruction urobilinogen is not formed and consequently it cannot appear in the urine regardless of the state of the liver. As initially determined, this patient exhibited a marked deficiency of prothrombin (Fig 62, PT). Within twenty-four hours after a single injection of vitamin K this returned to normal (Fig 62, PR). This rapid response suggested adequate hepatic function in this particular respect. Taken by itself only, the prothrombin response lent support to the diagnosis of extrahepatic biliary obstruction. The value of the blood cholesterol (Fig 62, TC) was not high, as one usually anticipates in extrahepatic obstructive jaundice. The positive cephalin cholesterol reaction, the failure to synthesize any hippuric acid after sodium benzoate injection and the altered plasma protein values, all suggested parenchymal liver damage.

Further measures were resorted to in an effort to analyze the hepatic function. In view of the absence of the native urobilinogen in the urine, the patient was subjected to the stercobilin tolerance test.²⁹ In the twenty-four hours following the intravenous injection of 50 mg of crystalline stercobilin, 30 mg of urobilinogen appeared in the urine (Fig 62, ST). This constituted evidence of a markedly reduced functional capacity of the liver in this respect. It must be pointed out, however, that long-continued biliary stasis often affects liver function adversely, and we have observed similar results with the stercobilin tolerance test in some cases of neoplastic biliary obstruction, although in some instances the results are entirely normal. In contrast with the stercobilin tolerance test the galactose tolerance test in this case (Fig 62, G) was within normal limits. This

- UCP Urine coproporphyrin in γ per 24 hours
- USR Urine-stool urobilinogen ratio

contrast at once reveals the striking difference in the way different functions may be affected in the same case

The photomicrograph from the needle biopsy is shown in Figure 63 Dr J S McCartney of the Department of Pathology reported as follows on this section

"This piece of tissue shows parts of at least 8 liver lobules, in two of which the central veins are recognized The liver cells are markedly pigmented There are many bile thrombi The portal tissues are greatly increased in extent with fibrous tissue There are large numbers of newly formed bile ducts in these spaces There is little or no leukocytic infiltration in any portal space

"Conclusion Cirrhosis of the liver with jaundice"

After establishment of the diagnosis, dietary therapy was promptly instituted The patient showed little or no improvement on a regimen of a high protein,

Fig 63 (Case I) —Photomicrograph from needle biopsy of the liver

high carbohydrate, low fat diet fortified with vitamin concentrates Choline hydrochloride, 1 gm daily, was administered for a period of one month without appreciable benefit Three months after discharge from the hospital, the patient expired Autopsy was not performed

In an analysis of this case, one may find clinical and laboratory evidence to support the diagnosis of extrahepatic biliary obstruction due to cancer, or to support the diagnosis of cirrhosis of the liver Consequently the information obtained by needle biopsy of the liver performed at the bedside was of the greatest aid

CASE II—C. K., a markedly obese housewife aged 56 years, presented a difficult diagnostic problem because of certain features suggesting parenchymal liver disease as the cause of her jaundice Six weeks prior to her hospital admission she

experienced her first attack of colicky right upper quadrant pain. This was followed, after a two-week period of anorexia, by jaundice associated with the passage of light colored stools and dark urine, and by pruritus. Prior to the onset of her presenting illness she had noted no intolerance to fatty foods and had been a hearty eater as evidenced by her weight, which was 240 pounds. Physical examination revealed the presence of jaundice several typical spider nevi were present on the anterior chest surface. Because of the marked obesity abdominal examination was unsatisfactory, the liver dullness was less than normal as determined by percussion. Ascites was not demonstrable; edema of the legs, however, was prominent.

The results of the composite liver function study are depicted graphically in Figure 64. The high serum bilirubin, negligible urobilinogen excretion, together

Fig 64 (Case II)—Liver function study August 25 to September 3 1944. Working diagnosis Biliary Tract Cancer or Cirrhosis. Final diagnosis Cancer of Gallbladder and Common Bile Duct. (For key to column designations, see Fig 62.)

with the elevated cholesterol and phosphatase values and the negative cephalin cholesterol, all point to a complete, extrahepatic biliary obstruction as a cause of the jaundice. The decreased plasma protein, the failure of the prothrombin value to return to normal suggest parenchymal liver damage. The validity of the low hippuric acid value is open to question since the phenolsulfonphthalein excretion during the test was only 8 per cent. Obstructive jaundice of four weeks duration does not ordinarily disturb liver function to such a degree as was evident in this instance. Allen and Julian¹¹ cite a case of extrahepatic obstruction in which the prothrombin time failed to return to normal after adequate vitamin K therapy. That patient had common duct stones; liver biopsy revealed inflammatory changes. The appearance of spider nevi as in this case is distinctly unusual in cases of jaundice due to extrahepatic biliary obstruction.

Liver biopsy by the needle technic was not believed safe in this instance. Peritoneoscopy was considered, but abandoned in favor of exploratory operation. This decision was reached when the patient developed fever and increasing leukocytosis on the tenth hospital day. Despite the controversial evidence, the most likely diagnosis appeared to be carcinomatous biliary obstruction with cholangitis. At the time of operation, the surgeon, Dr Richard Varco, found the gall bladder to be distended and thin walled. About the gallbladder bed numerous tumor masses were found. Biopsy of one of these masses revealed squamous cell carcinoma. Biopsy of the liver was performed at operation, and the section is shown in Figure 65. This revealed a slight increase in the portal tissue mainly

Fig 65 (Case II)—Biopsy of liver secured by the surgeon at time of operation. Extrahepatic obstructive jaundice, biliary tract carcinoma.

of the bile ducts. Numerous bile thrombi were present, no areas of necrosis were seen. Very little fat was noted.

The gallbladder was drained, a great deal of partially hemolyzed blood was found mixed with bile. Culture of this revealed aerobacter only. The patient lived but a few days postoperatively. Permission for autopsy could not be obtained. The final diagnosis was carcinoma of the gallbladder with metastases locally, and obstructive jaundice, extrahepatic in type. Of particular interest was the disturbed liver function and the presence of spider nevi simulating hepatic cirrhosis.

CASE III—S W., a woman aged 62, had as her chief complaint a generalized pruritus for a few years. Despite this she had not previously sought medical advice. The presence of jaundice was obvious on the first examination although the patient herself had not been aware of it. Physical examination revealed generalized brownish pigmentation of the skin, jaundice of the sclerae and a moderate degree of undernutrition. The liver and spleen were enlarged and easily palpable, there was no ascites although slight edema of the ankles was noted. Papular xanthomatous nodules were present over the Achilles' tendons and the

extensor tendons of the hands (Fig 66) The clinical impression was cirrhosis of the liver possibly of the xanthomatous biliary type

Fig 66 (Case III).—Xanthomatous nodules along the tendon sheaths. Xanthomatous biliary cirrhosis.

Fig 67 (Case III).—Needle biopsy of the liver Interpreted as portal cirrhosis.

Needle biopsy of the liver was carried out at the bedside. The histologic diagnosis from this biopsy was that of portal cirrhosis (Fig 67) A composite

and phosphatase studies, the entire picture would have been compatible with the diagnosis of ordinary cirrhosis of the liver. The enlarged liver and spleen and the jaundice without ascites suggest use of the term "Hanot's hypertrophic cirrhosis" although the age is not characteristic. While we cannot distinguish this group histologically, we recognize the clinical partition of cases of chronic jaundice, pruritus, hepatosplenomegaly and absence of ascites or of plasma albumen reduction. It is in this group that hypercholesterolemia and hyperphosphatasemia are likely to be encountered, and some few of the cases, as in the present instance, have the full-blown clinical picture of xanthomatous biliary cirrhosis.

Fig 69 (Case IV) —Liver function study, September 20 to September 23, 1943.
Working diagnosis Diabetes and Cirrhosis. Final diagnosis Hemochromatosis.
(For key to column designations, see Fig 62.)

CASE IV—C. K., a farmer aged 59 years presented with the complaints of weakness, weight loss and urinary frequency. Physical examination revealed considerable pigmentation of the face, hands and arms. The liver was definitely enlarged, the spleen was not palpable. No other abnormalities were noted. Routine urinalysis revealed glycosuria and further studies confirmed the diagnosis of diabetes mellitus. The diabetes was easily controlled by dietary measures and administration of 35 units of insulin daily.

The composite liver function study is shown in Figure 69. In view of the hepatomegaly the results of the study were surprising. Only very slight deviations from normal are seen. The native urine urobilinogen was moderately elevated so that it was unnecessary to perform the stercobilin tolerance test. As a supplementary procedure, the bilirubin tolerance test was performed (Fig. 69).

Fig 70 (Case IV) —Needle biopsy of the liver Extensive cirrhosis with some new bile ducts Note the darker masses within the hepatic cords (Hematoxylin and eosin stain)

Fig 71 (Case IV) —Needle biopsy of liver as stained with Berlin blue, dark masses are a deep blue color

BT) The result was entirely negative This was a distinct surprise in view of the extensive histologic changes in the liver The bilirubin tolerance test is regarded by many as a delicate measure of hepatic function In our experience it has not proved to be a very useful or consistent test for clinical purposes

CIRRHOSIS OF THE LIVER 37

Because of the presence of diabetes, skin pigmentation and hepatic enlargement, the diagnosis of hemochromatosis was considered. Biopsy of the skin revealed melanin only, the sections failing to reveal any hemosiderin. The dermatologists considered that the melanosis was probably due to exposure. Needle biopsy of the liver however, clearly revealed extensive hemochromatosis and cirrhosis (Fig 70). The dark granular masses within the hepatic cords proved to be iron when stained microchemically (Fig 71).

In view of the extensive histologic changes demonstrating more in the way of cirrhosis of the liver, the most helpful

In view of the extensive histologic changes found, the difficulty in demonstrating more in the way of functional alteration is notable. Biopsy of the liver, performed in this instance at the bedside, was the most helpful procedure in determining the correct diagnosis.

gastrointestinal tract and urinary tract failed to demonstrate any evidence of a primary tumor. The composite liver function study (Fig 72) performed in July, 1943, pointed to lowered hepatic function as indicated by retention of bromsulfalein and excessive urobilinogenuria. The other tests, however, yielded normal results and jaundice was absent. These results permitted no definite conclusion as to the pathology present.

Needle biopsy of the liver was performed at the patient's bedside. This revealed the presence of amyloid disease (Fig 73), a finding which was totally unexpected in view of the absence of any chronic suppuration or evidence of a neoplasm. Because of some hesitation to accept this diagnosis, the biopsy of the liver was repeated at a site somewhat removed from the former and over an area that felt nodular to palpation. The histologic examination of this second biopsy appeared to be identical with the first. In both sections, the pathologist described sheets and strands of pale-staining, faintly eosinophilic material. In some areas

Fig 73 (Case V) —Needle biopsy of the liver, amyloid disease

this material could be seen to be definitely lining the sinusoids. The conclusion was amyloid disease of the liver.

A Congo red test performed after this information was obtained revealed 55 per cent left in the blood stream at the end of one hour.

The patient was released from the hospital. In September, 1943, he returned. Examination at this time revealed marked ascites and a greater degree of emaciation. The liver was still enlarged and the character of its surface was about the same as it had been on the previous admission. There was no visible jaundice but the serum bilirubin was 15 mg per 100 cc. The composite liver function study was repeated (Fig 72). This revealed a peculiar pattern from which no definite conclusion could be drawn. Peritoneoscopic examination was carried out during this admission. The surface of the liver as visualized appeared free of any tumor nodules. No abnormalities other than the presence of ascitic fluid were noted. Needle biopsy of the liver performed during peritoneoscopy again revealed amyloid disease. The patient remained alive for six weeks during which time he developed jaundice, later signs and symptoms suggesting adrenal insuff-

ficiency appeared. The latter was characterized by hypotension and hemoconcentration. There was temporary response to administration of adrenal cortical extract. Permission for autopsy was refused.

This case was assumed to be an example of primary systemic amyloid disease although an occult carcinomatosis or tuberculosis could not be excluded. The diagnosis of amyloid disease probably would not have been possible, here, without liver biopsy. A second similar case has been seen in which amyloid disease of the liver was demonstrated, and again no evidence of primary tumor or of tuberculosis could be ob-

Fig 74 (Case VI) —Liver function study October 6 to October 13 1944
Working diagnosis Biliary Tract Carcinoma or Cirrhosis or Pericholangitic
Hepatitis (For key to column designations, see Fig 62)

tained. The principal features of the latter case were hepatomegaly, ascites, albuminuria and edema. Jaundice was absent. Two needle biopsies of the liver revealed amyloid disease. Autopsy permission in this case was also denied.

CASE VI—O R., a man aged 36 years, was seen three months after the onset of painless jaundice. The patient appeared well developed and well nourished. The liver was greatly enlarged, firm and somewhat nodular. The diagnostic possibilities here, at the outset included (1) carcinomatous biliary obstruction with biliary obstructive cirrhosis or with metastases and (2) pericholangitic hepatitis or cirrhosis. The age and history somewhat favored the second but the feeling of the liver was more suggestive of the first.

Fig 75 (Case VI) —Needle biopsy of the liver Pathological report early obstructive biliary cirrhosis

Fig 76 (Case VI) —Liver biopsy secured at time of peritoneoscopy Metastatic carcinoma adjacent to liver tissue

The composite liver function study is shown in Figure 74. This revealed a pattern indicative of complete extrahepatic biliary obstruction as seen more often with cancer. Needle biopsy of the liver was performed. A satisfactory strip of tissue was obtained which revealed evidence of nothing more than early biliary obstructive cirrhosis (Fig. 75). It was felt that the histologic changes noted could be due to long-standing biliary obstruction but the cause of this obstruction remained in doubt. The patient was therefore subjected to peritoneoscopic examination. This revealed clearly the presence of whitish nodules of various sizes on the surface of the liver. The long biopsy needle was inserted through the anterior abdominal wall and a specimen of the edge of one of the nodules was secured while the liver surface was viewed through the peritoneoscope. This biopsy revealed typical adenocarcinoma with some relatively normal hepatic cords (Fig. 76). The primary source of the carcinoma was not determined. The gallbladder as visualized during peritoneoscopy was not greatly distended. The fundus was free but the neck and cystic duct, insofar as could be seen, were involved by tumor. It was thus established that the cause of the jaundice was cancer and that this was inoperable. In this instance peritoneoscopy was the most helpful of the various methods employed, although the composite liver function study was strongly indicative of the correct diagnosis.

Needle biopsy of the liver when carried out as a bedside procedure is of aid in recognizing metastatic carcinoma in the liver only if the needle happens to enter a tumor nodule. Should the needle pass between the nodules, as in the case of the first biopsy in Case VI, only liver tissue is obtained and the procedure is of little value. Occasionally in the presence of suspected tumor nodules in the liver, one may feel them along the inferior margin. There is a temptation to attempt to insert the needle directly into one of them, but this is undoubtedly dangerous because of the proximity of the bowel. In such instances peritoneoscopic examination should be resorted to if the tumor nodule biopsy is deemed necessary.

CASE VII.—D. T., a laborer aged 53 years, was admitted to the University Hospital with the complaint of a dull constant epigastric pain. There had been no nausea or vomiting. Constipation had been troublesome and he had suffered from intermittent generalized abdominal cramps associated with distention and a sensation of heaviness across the lumbar portion of his back. A detailed study in the Out Patient Clinic including laboratory and x-ray examinations had failed to yield a diagnosis. The epigastric pain had persisted for about six months.

Physical examination revealed the patient to be well developed and well nourished. There were no abnormalities noted. The abdomen was slightly distended and tympanitic. No masses were palpable. There was no adenopathy. In the differential diagnosis, atrophic cirrhosis was strongly considered and the abnormalities noted in the results of the composite liver function study tended to confirm this diagnosis (Fig. 77). The marked urobilinogenuria, the positive cephalin cholesterol flocculation and the marked bromsulfalein retention suggested parenchymal liver dysfunction. There was an absence of any qualitative or quantitative changes in the blood picture (hemoglobin 12.7 gm per cent erythrocytes 4.3 millions, leukocytes 10,300 with 73 per cent neutrophils, 25 per cent lymphocytes, 1 per cent monocytes and 1 per cent eosinophils).

During the second week of hospitalization the patient developed ascites. This made the diagnosis of cirrhosis seem all the more likely. At no time was enlargement of the liver or spleen noted. Peritoneoscopy was performed at this

time ascitic fluid was removed. The fluid was sterile and of low specific gravity (1.006). The liver appeared pale and finely granular. It did not have the usual appearance of cirrhosis, yet there was nothing to suggest metastatic carcinoma. Needle biopsy of the liver was performed. Bleeding, as observed, was not marked in spite of the fact that the prothrombin time was elevated and could not be returned to normal by the parenteral administration of vitamin K (Fig 77 PR). The strip of tissue obtained, while of the usual size, was hardly recognizable as liver. Large portions of the section appeared to be made up of necrotic cells (Fig 78) and one or two cords of cells embedded in fibrous tissue suggested atypical tumor cells. The final conclusion was "partially necrotic malignant tumor of liver."

The patient later developed jaundice and became comatose. He expired on the twenty fourth day of hospitalization. Autopsy disclosed the presence of Hodgkin's disease involving the liver and spleen.

The clinical features of this case suggested cirrhosis, the liver biopsy was not interpreted as Hodgkin's disease, but after the autopsy had confirmed this diagnosis it was recognized that the biopsy had suggestive areas.

Fig 79 (Case VIII) —Liver function study, October 17 to November 10, 1942. Working diagnosis: Biliary Tract Cancer or Cirrhosis. Final diagnosis: Cancer of Gallbladder and Common Bile Duct. (For key to column designations see Fig 62.)

CASE VIII —H C., a housewife aged 41 years, was admitted to the University Hospital because of the presence of jaundice, ascites and right hydrothorax. The jaundice had appeared four months previously. It was painless in onset. One week prior to the onset of the jaundice the patient had undergone a minor pelvic op-

eration (uterine dilation and curettage) at her local hospital Chloroform had been used as the anesthetic agent. Jaundice had been present about two months before the development of ascites Shortly before admission to this hospital, the patient had received vitamin K therapy from her physician Review of her past history revealed good health on the part of the patient, there was no evidence of chronic alcoholism and the only exposure to a toxic agent was the above mentioned chloroform

Physical examination revealed a deeply jaundiced woman of the stated age, she appeared in no acute distress The presence of hepatomegaly, ascites and right hydrothorax constituted the chief physical findings Routine laboratory studies revealed the presence of a mild anemia, macrocytic normochromic m type Composite liver function studies (Fig 79) revealed a pattern suggesting

Fig 80 (Case VIII) —Needle biopsy of liver, pattern that of obstructive jaundice extrahepatic in type

complete biliary tract obstruction without much evidence of parenchymal liver damage The hippuric acid excretion was reduced and the galactose and sterco-bilin tolerance tests revealed some abnormality There is no doubt, however, that extrahepatic obstructive jaundice at times exhibits this much evidence of parenchymal disturbance Needle biopsy of the liver was performed This revealed many bile thrombi, no increase in portal connective tissue and no fatty changes (Fig 80) The pathologist, Dr J S McCartney, concluded that the appearance was that of extrahepatic biliary obstruction

The pleural and ascitic fluids were repeatedly aspirated and searched for tumor cells None were ever found The clinical impression was that the patient was suffering from cancer of the biliary tract and that, in view of the ascites and pleural effusion, metastases had already occurred The chloroform exposure was judged to be merely a coincidental matter as regards the cause of the jaundice. This proved to be correct The patient expired three months later Autopsy disclosed an extensive scirrhous carcinoma of the common bile duct with local and distant metastases

SUMMARY AND CONCLUSIONS

1 A series of cases of liver disease has been presented involving either cirrhosis or conditions in which the diagnosis of cirrhosis had to be considered. These cases illustrate many of the difficulties commonly encountered in the differential diagnosis of this group of diseases.

2 A composite liver function study has been found to be helpful. The results are recorded on a standard form permitting ready comparison of the disturbance of individual functions, together with the degree of jaundice and the degree of biliary obstruction.

3 Certain forms of cirrhosis or other liver disease, as well as extra-hepatic biliary obstruction exhibit fairly characteristic "profiles" on the composite liver function chart. It is recognized, however, that much experience must be gained before strict differentiation will be feasible on the basis of such studies, and it is certain that they will never do more than supplement the history and physical examination in any given case.

4 Liver biopsies have been carried out in seventy cases of liver disease, fifty of which were done at the bedside and twenty in the operating room under peritoneoscopic control. The Vim-Silverman needle was used in all instances. Attempts to secure a biopsy were unsuccessful in fifteen additional cases, most of which were in the earlier period of the study. A serious but nonfatal hemorrhage occurred in one instance.

5 It is believed that the conjunction of the composite liver function study with liver biopsy has permitted much additional insight into the pathologic physiology of jaundice and liver disease. From these studies it has become increasingly apparent that cirrhosis of similar anatomic extent may exhibit strikingly different degrees and types of liver functional impairment. The diagnosis of obscure or uncommon liver disorders, as for example, primary amyloidosis, has been established by biopsy in cases in which the composite liver function study, above, although abnormal, was not diagnostic.

HYPERPARATHYROIDISM

EDMUND B FLINK, MD •

HYPERPARATHYROIDISM is a disease of the parathyroid glands with its chief manifestations in the musculoskeletal and genitourinary systems. Von Recklinghausen¹ first described the skeletal manifestations of the disease in 1891 and differentiated osteitis fibrosa cystica from osteomalacia and osteoclastic metastases to bone.

Askanazy² was the first to comment on the presence of a parathyroid tumor in a case of osteitis fibrosa cystica. Erdheim³ pointed out that the parathyroids undergo hyperplasia in osteomalacia and other bone diseases. He postulated that the abnormal amounts of calcium and phosphorus liberated from the decalcified skeleton caused hyperplasia of the parathyroids and thought therefore that in osteitis fibrosa cystica the parathyroid enlargement was a secondary phenomenon. Successful surgical removal of a parathyroid adenoma by Mandl⁴ in 1925 with subsequent recovery of the patient disproved the belief that the parathyroid pathology was secondary to the bone disease. During the past nineteen years a great number of cases have been reported. As an illustration of the prevalence of the disease, the group of investigators at the Massachusetts General Hospital alone have treated over seventy such patients.⁵

REPORT OF CASES

In order to illustrate certain diagnostic criteria and results of treatment six cases seen during the past four years at the University of Minnesota Hospitals will be reported. Particular note should be given to the skeletal and genitourinary symptoms in these cases.

CASE I.—F W., a 45 year old woman, was admitted to the hospital in June 1940. Her illness had begun insidiously six years earlier manifesting itself as muscular weakness. She had had bilateral chronic otitis media since childhood. In 1935 she had an episode of urinary frequency and nocturia but no polyuria at any time. In January 1940 an epulis was removed from the right maxilla. In March 1940 pain and a vague mass appeared in the right thigh. In April 1940 she fractured the shaft of the femur on arising from a chair. A hip spica cast was applied at another hospital. Menopause began in April 1940. The blood pressure was 104/70. There was bilateral chronic otitis media with drumhead perforations and serous drainage from each ear. Hearing was impaired moderately. A hip spica enveloped the lower body and right lower extremity. The rest of the general examination was negative.

From the Department of Medicine, University of Minnesota Hospitals, Minneapolis, Minnesota.
Assistant Professor of Medicine, University of Minnesota.

Urinalysis and blood chemistries are recorded in Tables 1 and 2 for this and subsequent cases. The hemoglobin level was 11.4 gm per 100 cc., erythrocytes numbered 4,590,000, there were normal leukocyte and differential counts.

X-rays showed pathologic fracture of the right femur at the site of a cyst, generalized decalcification of the skeleton, coarsening of the trabeculation especially in the bones of the hands, feet and left tibia, thinning of the cortex of all bones and absence of the usual diploic marking of the skull. All these indicated a typical example of osteitis fibrosa cystica generalisata. In addition there was chronic mastoiditis.

On July 1, 1940, Dr. John R. Paine removed an adenoma of the parathyroid located in the lower pole of the right lobe of the thyroid. The adenoma weighed 3 gm and was composed of chief cells predominantly. The postoperative course was complicated by mild tetany which was controlled satisfactorily by dihydroxyacetone phosphate and calcium lactate orally. The femur fracture gradually healed. The patient's skeleton has not become completely normal after two years of follow-up, but the biochemical findings returned to normal. A mastoidectomy was carried out in 1941.

CASE II—R. S., a 38 year old woman, was admitted to the hospital in December 1941. She had noticed weakness, marked fatigability and tenderness of her knees for two years or more together with polydipsia and polyuria for seven or eight years. She had been moderately constipated for three or four years. Her principal presenting complaint was a mass in the region of the lower right molars noted first in September 1940. This mass when biopsied proved to be a giant cell tumor. X-rays of the skeleton were obtained elsewhere and she was sent to the hospital with the tentative diagnosis of hyperparathyroidism.

On examination the patient was well developed and her pulse and temperature were normal. Her blood pressure was 164/90. There was a small hard mass near the middle of the right mandible. A small mass palpated in the right side of the neck moved on swallowing. There were no areas of skeletal tenderness. The liver margin was palpable at the costal margin. The tendon reflexes were hyperactive.

The hemoglobin level was 13.5 gm per 100 cc., leukocytes and differential counts were normal. The Wassermann reaction was negative. Electrocardiograms before operation showed a first degree heart block (P-R interval 0.22 and 0.23 seconds) and an inverted P_3 . Seventeen days after operation the P-R interval had returned to normal (0.16 seconds), P_3 was upright, and the amplitude of the QRS complexes and the T waves in all leads was greater than on the initial tracing. X-ray films of the pelvis, skull, mandible, hands, long bones, vertebral column and chest revealed multiple cysts in these bones, striking nodular decalcification of the skull and generalized decalcification of the whole skeleton. There were multiple areas of calcification in the kidney parenchyma and stones in the pelvis of the right kidney.

Dr. John R. Paine carried out a subtotal resection of a large parathyroid adenoma on December 17, 1941. Ten grams were removed from the adenoma of the right superior parathyroid gland. The patient did not develop tetany postoperatively. She was readmitted to the hospital in June 1942 for removal of the remainder of the adenoma which weighed 1 gm. The adenoma was composed of chief cells predominantly. At the second admission she had renal colic and hematuria. In April 1942 there was a remarkable improvement in the appearance of the skull and in July 1942 the appearance of the whole skeleton had returned nearly to normal. The patient's weight has increased, she is able to do all of her own work, she no longer is troubled with constipation, her polydipsia is alleviated and her strength is normal. Her blood pressure was 200/110 in January 1944 and at the last visit to the clinic in August it was 146/92.

CASE III—A S., a 57 year old woman, had noted a mass in the left side of her neck for five or six years. Eructations of food began in April 1942 and vomiting after meals with serious dehydration developed in July 1942. After a period of hospitalization elsewhere her condition improved symptomatically but she was an invalid most of the time until her admission to this hospital in December 1942. Vomiting after meals and marked anorexia continued until this time. She had lost about 30 pounds of weight in all, was unusually nervous and irritable and so weak that she could not work at all. She had been constipated for many years. For five years she had noted polyuria and polydipsia but no renal colic at any time. Only on direct questioning did she admit having had some aching pains in the extremities and back.

On examination the patient's pulse was 100 and her temperature was normal. Her blood pressure was 196/114. She was tall and very malnourished, weighing 87 pounds on admission. The retinal arterioles were attenuated and there were moderate arteriosclerotic changes. A small nodular mass was located just below the thyroid cartilage on the left side in the region of the medial portion of the left lobe of the thyroid. The heart was moderately enlarged to the left. There was some thoracic kyphosis. Slowly moving peristaltic waves were visible over the stomach and small intestine. Neurologic examination was essentially negative.

Hemoglobin was 9.0 gm. per 100 cc. erythrocytes numbered 4,400,000 there were normal leukocyte and differential counts. The blood urea nitrogen obtained during the period of dehydration and eventual oliguria from fluid restriction and polyuria rose from 22 mg. per 100 cc. to 56 mg. per 100 cc. but returned to normal in twelve days. The basal metabolic rate was plus 3 per cent.

X ray films of the skull, hands, mandible, spine and long bones showed only osteoporosis consistent with her age and sex. The excretory urogram revealed poor excretion and suppled areas of calcification throughout the cortical portions of both kidneys. Chest films revealed metastatic calcification in the bronchi. The gastrointestinal tract was negative for intrinsic lesions but there was definite hypomotility of both stomach and intestine with very slow emptying time.

During preliminary investigation fluids were restricted for various reasons on four successive days. The polyuria was so marked that the patient lost 8 pounds of weight in that period and exhibited definite dehydration phenomena. On December 29, 1942, Dr. Richard Varco removed a chief cell adenoma composed of four lobules and weighing 4 gm. Three normal-appearing parathyroid glands were identified. The postoperative course was uneventful. The patient developed a moderate amount of edema during the subsequent month but this subsided following simple salt restriction and has not recurred. In four months she had gained 20 pounds in weight, was much stronger, was able to be up all day, was able to eat without vomiting and was no longer constipated. She has no polydipsia now. She is able to work as a maid all the time and her only symptom is the occurrence of an occasional severe headache. Her blood pressure was 220/120 at the last clinic visit twenty-one months after operation.

CASE IV—I O., a 57 year old woman, noted the onset of pain in the right wrist in July 1942 and in the right leg in September 1942. Severe pain on weight bearing developed in February 1943 causing her to become an invalid partially bedridden. She had noted swellings in the right forearm and right leg about the same time, and had lost 25 pounds in a year. She had polyuria and polydipsia on occasion but no renal colic or hematuria. A biopsy of the mass on her arm performed by her own physician revealed a giant cell tumor.

On examination the pulse and temperature were normal. The blood pressure was 114/78. Fusiform swellings were palpated along the midportion of the right leg and right forearm. The masses were definitely warmer than the surrounding tissue, and weight bearing caused pain. The hemoglobin was 10.9 gm. per 100 cc.

erythrocytes numbered 3,800,000, leukocytes 4100, with neutrophils 40 per cent, lymphocytes 56 per cent, monocytes 4 per cent

X-ray examination showed multiple cysts of the long bones, pelvis, skull, mandible, ribs and hands with generalized decalcification and coarsening of trabeculi. Very large multiloculated cysts in the right ulna and right tibia and multiple stones throughout both kidneys were also present. Fluoroscopy revealed a mass in the posterior superior mediastinum behind and to the right of the esophagus.

A parathyroid adenoma weighing 3 gm was removed by Drs B G Lannin and C Dennis on May 26, 1943. Postoperative tetany did not develop though the serum calcium dropped as low as 8.5 mg per 100 cc. The patient did not return to the clinic until October and then she was having recurrent pain in the right arm and leg. X-rays revealed further decalcification and new cyst formation, and she had suffered a fracture of the right tibia by stepping on a scale. She was readmitted to the hospital. A mass in the mediastinum was again demonstrated. On November 13, 1943, Dr Dennis found a parathyroid tumor in the posterior superior mediastinum and another in the substance of the left lobe of the thyroid, weighing 18 gm and 2 gm respectively. One apparently normal sized parathyroid was identified in the right superior position.

The true pathologic nature of the tumor was not appreciated until review of the sections immediately after the second operation. The histological appearance was typical of that described by Castleman and Mallory⁶ as primary hyperplasia of the "wasserhelle" cells. Postoperative tetany did not occur. The patient improved gradually and gained weight, but has had bone pain from time to time. A letter from her in August 1944 stated that she was feeling better than she had for a long time, but she had not returned to the clinic for determinations of serum calcium, and so on. One cannot say that she is cured at the present time, but she is improved.

CASE V—S F (Reported through the courtesy of Dr George Levitt of St. Paul, Minnesota.) This 40 year old woman was admitted to the University Hospital in December 1943 for the confirmation of a diagnosis of hyperparathyroidism. In the early part of 1940 she had a vaginal hysterectomy for excessive uterine bleeding (benign). Immediately thereafter she noted severe pains in her lower back and left hip and thigh. These pains were excruciating on any kind of weight-bearing but were present to some degree all the time. Muscle weakness since the onset in 1940 had prevented her from performing more than a part of her household duties and had resulted in complete exhaustion on walking two blocks. During 1943 the pains in the legs, hips, ribs and upper back were constantly present, and deformity of the terminal phalanges of both hands began and progressed without any noticeable joint involvement. Since 1940 she had had bouts of polydipsia and polyuria but no other renal symptoms.

On examination the pulse and temperature were normal. The blood pressure was 138/80. A moderate thoracic kyphosis was evident. A mass which was vaguely defined was present under the origin of the sternocleidomastoid muscle in the region of the lower pole of the left lobe of the thyroid. Tendon reflexes were equal but slightly hyperactive. There was marked deformity of the hands, most marked in some of the terminal phalanges but also present in some of the middle phalanges.

The hemoglobin was 13.6 gm per 100 cc, leukocytes numbered 4350, with neutrophils 60 per cent, lymphocytes 36 per cent, monocytes 2 per cent and eosinophils 2 per cent. The Kline exclusion test was negative.

X-ray films taken elsewhere in 1941 showed changes in the skull, ribs, hum

crus, pelvis and thoracolumbar spine with decalcification and tendency to cyst formation. Typical changes of osteitis fibrosa cystica generalisata with especially marked changes in the phalanges of the hands were present in 1943.

The patient was referred to Dr. Oliver Cope of the Massachusetts General Hospital who removed a chief-cell adenoma of a parathyroid gland. Mild symptoms of tetany developed immediately postoperatively but the symptoms have been completely alleviated. Eight months after operation the calcium phosphorus and phosphatase values were normal.

CASE VI—G. M., a 59 year old man, was admitted to the hospital on April 2, 1944. Two years before he fell and injured his left knee. The injury was treated by the application of a cast, but it was not certain whether he had a fracture. Since that time he had had pain in the lower back, in the hips and both lower extremities. The pain was deep-seated, often shooting in character and severe enough to require opiates for relief. The patient had been weak for twelve years and for three years the weakness had been progressively interfering with his work. For twenty five years he had had polydipsia of varying intensity and had had to drink as much as 2 gallons of water some days. There had been no other renal symptoms. He had lost 30 pounds during the past several years in spite of a good appetite.

Examination showed a well developed but very poorly nourished man weighing 120 pounds. His blood pressure was 113/72. A small mass was palpable below the right sternocleidomastoid muscle at the level of the lower pole of the right lobe of the thyroid. This mass moved on swallowing. He had a lumbar lordosis and a slight thoracic kyphosis. There was slight inequality of the tendon reflexes, but sensory examination was normal.

Hemoglobin was 12.1 gm per 100 cc., erythrocytes numbered 3,760,000, leucocytes and differential count were normal. The blood urea nitrogen was 45 mg per 100 cc. and the creatinine 2.3 mg per 100 cc. before surgery. Several weeks after surgery the blood urea nitrogen had decreased to 17 mg per 100 cc. An electrocardiogram revealed a P-R interval of 0.20 seconds.

On x-ray the skull showed an extremely granular appearance similar to that of patient II. Some rarefaction of the mandible was evident as well as a marked osteoporosis of the hands with thinning of the cortices of the small bones, erosion of many of the distal phalanges and fracture of some of the terminal tufts. Both tibiae and fibulae showed extensive decalcification with some granularity and thinning of the cortex. There was evidence therefore of a severe form of osteitis fibrosa cystica generalisata.

In May 1944 Dr. Richard Varco removed a parathyroid tumor weighing 20 gm from the region of the lower pole of the right lobe of the thyroid and the subclavicular area. The adenoma was composed of chief cells predominantly. In some areas there was a tendency to rosette formation and gland formation. Normal parathyroid glands were identified on the left side.

On the seventh postoperative day the patient had definite but mild symptoms of tetany. For several days his Chvostek and Trousseau signs had been positive and remained positive for four or five days thereafter. He received 1 gm of calcium gluconate on three occasions with satisfactory response. On the day of operation and during the whole postoperative period he received 3.75 mg of dihydrotachysterol and 6 to 24 gm of calcium lactate orally every day. In the three-month period from operation to the last clinic visit he had gained 15 pounds, was much stronger, was practically free of pain and his morale was much better. There had been a remarkable increase in the calcification of the skull and skeleton in general but not a complete return to normal.

COMMENT

Diagnosis—A clue to the diagnosis depends on the symptomatology which is characteristic of the disease. The musculoskeletal and genitourinary symptoms predominate, but gastrointestinal and cardiovascular symptoms may occur and may even be the presenting complaints.

The most prominent symptom of all is *pain in the bones and joints*. The six patients had a variable amount of pain. In Case VI the patient had so much pain that he had to take codeine frequently and was disabled for two years. His pain was erroneously thought to be due to polyneuritis when he was first seen at this hospital. In all of the patients the pains were not constant but were severe at times and practically absent at other times. Pain on weight bearing is an important symptom and should suggest some form of bone disease. This symptom could be elicited from five of the six patients. Direct questioning in Case III was necessary to elicit the history of mild pain in the bones and joints.

All patients exhibited *muscular weakness* which was marked enough to interfere with work, and even caused semi-invalidism of several patients. The muscular weakness is probably related to the hypercalcemia. It is interesting that some of the patients had hyperactive tendon reflexes.

An *epulis* was removed in the first two patients some time before the true nature of the disease was recognized. Epulides are well known in a small percentage of cases of hyperparathyroidism. Thannhauser⁷ reports the presence of epulis-like lesions in cases of bone disease associated with neurofibromatosis.

Deformities of any part of the skeleton may occur. There have been many patients with progressive decline in stature because of compression of the vertebral bodies, coxa vara, and bowing of the long bones. None of the six patients in the present series complained of change of stature, but several had moderate kyphosis. Deformities of the hands in Cases V and VI and tumefactions in some of the long bones in Case IV and in the femur in Case I were noted.

A pathologic fracture of the right femur was responsible for bringing the first patient to the care of physicians. Interestingly enough it was thought that she had metastatic carcinoma of the femur and she was transferred to this hospital for palliative x-ray therapy. *Fractures sustained by little or no trauma* certainly should suggest the possibility of hyperparathyroidism or some other decalcifying or cyst-forming process. They constitute presenting complaints of a fair percentage of patients with this disease.

Genitourinary Symptoms—A better understanding of the symptomatology referable to the genitourinary tract has resulted from the classification proposed for the renal pathology by Albright and associates.⁸ There are three main groups of lesions: (1) pyelonephritis secondary to formation of calcium phosphate stones, (2) nephrocalcinosis,

differing from the previous type in that the calcium deposits are in the kidney parenchyma rather than in the pelvis, and causing inflammatory changes, sclerosis and contracted kidneys, (3) acute parathyroid poisoning with calcium deposits in the kidney and all other organs, resulting in anuria and death. The symptoms associated with formation of stones in the pelvis or ureters are the same as those from any stone. Renal insufficiency may occur from hydronephrosis and pyelonephritis. Particular attention should be given to the symptoms of polydipsia and polyuria. Five of the six patients in this series had polyuria either constantly or intermittently before operation. The urine volumes were as high as 3000 cc. per day but averaged 1500 to 2000 cc. during hospital stay before operation. The cause of the polyuria is not entirely understood, but it was present in a patient with normal renal function and was alleviated after operation in all but one patient. It must be related in some way to hypercalcemia, hypercalciuria and hyperphosphaturia. In two patients (Cases III and VI) these symptoms were the first real clue to the diagnosis. It is entirely possible that a correct diagnosis would not have been made in Case III if they had not attracted attention to the possibility of hyperparathyroidism. The polyuria was so marked that dehydration occurred when fluids were restricted. The sixth patient was in the hospital for twenty days before the symptom complex of pain in the extremities and polyuria was recognized.

Cardiac irregularities and conduction defects occur occasionally. In Case II the patient had a prolonged P-R interval which returned to normal after operation. Elsom, Wood and Ravdin⁹ reported a patient with prolonged P-R conduction time which did not return to normal after removal of a parathyroid adenoma. Hypertension is related to renal insufficiency but patients IV and VI with renal insufficiency of a severity comparable to that of the two hypertensive subjects, had normal blood pressures. Snapper¹⁰ followed a patient with hypertension for two years after removal of a parathyroid adenoma and found persistence of the hypertension. The absence of hypertension in some patients with severe renal insufficiency has been noted by others.^{7, 9, 10} No striking improvement in renal function occurred in the patient reported by Elsom and his coworkers⁹ in one year following removal of a parathyroid adenoma. This has been the experience of others.^{8, 10} It is reasonable, however, to expect cessation of the progress of renal insufficiency by successful surgical treatment of hyperparathyroidism. In Cases III and VI a moderate improvement in renal function has been evidenced by a decrease in blood urea nitrogen to normal and an increase in phenolsulfonphthalein dye excretion. Hypertension has persisted in Cases II and III.

Many patients have *constipation* and *flatulence*, and some have marked *anorexia*, *nausea* and bouts of *vomiting*. The third patient had unusually severe gastrointestinal symptoms. She was admitted to the

hospital because of recurrent vomiting. She said "The food just doesn't go down." Pyloric obstruction was suspected clinically and a gastrointestinal study by barium meal was carried out. There was no obstruction but the stomach and bowel motility was very slow. Morelle and Beyerinck¹¹ have each reported an instance of similar severe gastrointestinal symptoms. One must consider this disease in patients with symptoms suggesting pyloric or intestinal obstruction.

Roentgenologic Diagnosis—The roentgenologist often suggests the diagnosis of hyperparathyroidism when it has been unsuspected clinically. Osteitis fibrosa cystica generalisata does not occur in all cases as illustrated in Case III, and especially in cases reported by Albright and his coworkers¹². The bone lesions are generalized when they are demonstrable. There is widening of the bone marrow space with thinning of the cortex. The diffuse widening of the Haversian canals becomes evident as increased porosity of the bones and increase in the coarseness of the trabeculation of bone. Cysts and giant cell tumors occur frequently but these are not necessarily present. The skull often has a very characteristic appearance. Unusual skull changes were seen in Cases II and VI. X-ray demonstration of renal calcification, calcium phosphate stones in the renal pelvis and metastatic calcification in other organs is very important information. Fluoroscopy, x-rays, and plainograms of the upper mediastinum are valuable in trying to locate adenomas in the mediastinum.

Biochemical Diagnosis—As valuable as x-ray diagnosis is in this disease, confirmation of the diagnosis depends on the biochemical findings in any given case. The essential features of the biochemical syndrome are as follows: (1) hypercalcemia, (2) hypophosphatemia, (3) hypercalcinuria, (4) hyperphosphaturia and (5) increase in the phosphatase content of the serum. Parathormone causes an increase in the serum calcium, reduces the serum phosphate, and in young animals especially will cause widespread bone disease similar to osteitis fibrosa cystica. Furthermore it has been amply demonstrated that parathormone causes a phosphate diuresis.

A complete calcium balance study was not carried out in any case of the present series, nor was phosphorus excretion studied. In Table I the chemical findings in the six cases are summarized. There are some unexplainable variations in the data, but for the most part the findings are self-evident. McLean and Hastings¹³ have demonstrated the importance of a consideration of serum protein in conjunction with serum calcium determinations, since the nondiffusible portion of the total calcium depends entirely on the protein concentration. In other words, lowering of serum proteins will lower the total calcium approximately 0.75 mg. for each gram of protein. The importance of this factor is especially evident in the interpretations of the serum calcium in Case III, when the calcium concentration was 9.8 mg. per 100 cc., the total serum protein was only 5 gm. per 100 cc.

Serum alkaline phosphatase units are expressed as King-Armstrong units/100 cc.

† Preoperative values on encephalopathy.

Serum alkaline phosphatase units are expressed as King-Armstrong units/100 cc. serum in all instances except the first marked B.U. = Bodanaky Units.

† Preoperative values on successive days were obtained when the patient was eating a general diet often with extra calcium.

‡ Numbers in parentheses indicate number of months after operation.

§ Postoperative values were obtained when the patient was eating a general diet and this postoperative values were obtained when the patient was eating a general diet.

In a review of 114 cases of hyperparathyroidism in which the serum calcium concentration was recorded, Gutman and coworkers¹⁴ found that 109 had over 11 mg and 91 had over 12 mg per 100 cc. In 79 cases in which the serum inorganic phosphorus was recorded 35 cases had values less than 2.5 mg per 100 cc. Albright and associates¹² reported a number of instances of proven hyperparathyroidism in which the average calcium concentration of the serum was below 12 mg per 100 cc and in which the serum phosphatase activity was entirely normal. These patients had symptoms referable to genitourinary tract calculi and were classed as "cases with a minimal degree of hyperparathyroidism." The average preoperative serum calcium values reported in this series of 35 cases ranged from 10.6 to 17.3 mg per 100 cc. It is important to recognize that when serious renal insufficiency and uremia supervene, the phosphorus may be normal or even high and consequently the serum calcium may be normal or even low. Many authors have emphasized the importance of repeated calcium determinations in a case of suspected hyperparathyroidism and one can understand the importance of this when one reviews the data in Case III and in other reported cases. For instance Wilder and associates reported a case with extreme skeletal decalcification having serum calcium values of 11.5, 11.0, 10.6 and 11.0 mg per 100 cc.

Calcium excretion in the urine is an important confirmatory test, especially when the results of the chemical analysis of the serum are unconvincing. This was of crucial importance in Case III. The qualitative Sulkowitch test¹⁶ indicates roughly the presence of abnormal amounts of calcium, but because of variations in specific gravity and volume of the urine from time to time, quantitative information is to be preferred. The urine calcium determinations in the present study were carried out by an adaptation of the Sulkowitch test for use with the Evelyn photoelectric colorimeter. The turbidity formed by the calcium oxalate precipitate depends on the quantity of calcium oxalate and can be measured with the colorimeter quite accurately. A low calcium neutral-ash diet was given preoperatively but high calcium intakes were given postoperatively. A normal person excretes 100 mg calcium or less in the urine daily when taking the above diet. All of the patients in the present series had increased excretion of calcium. It may be noted that patient VI had lower calcium excretion than the others but his renal function was seriously impaired. Snapper¹⁰ reported a case in which the urine calcium excretion was entirely normal, but his patient had renal insufficiency as evidenced by slightly elevated blood urea and nonprotein nitrogen. Downs and Scott¹⁷ reported a case with an excretion of but 24 mg of calcium per day during the phase of uremia. A negative calcium balance and a high excretion of calcium in the urine also occur in hyperthyroidism, in multiple myeloma, and in Paget's disease of bone. These conditions have to be dis-

† Numbers in parentheses indicates number of months after operation.

ferentiated from hyperparathyroidism by serum calcium and phosphorus determinations and evidence obtained by x-ray examinations.

The *alkaline phosphatase activity of the serum* is considered to indicate the activity of the mechanism of bone repair even though in hyperparathyroidism osteoclasts is the process most evident histologically and by x-ray. There are many other conditions of the bone in which the phosphatase activity is increased, particularly in Paget's disease of bone, in rickets, in osteomalacia, in certain cases with carcinomatosis of the skeleton and in extensive fractures. In multiple myeloma and Ewing's tumor the phosphatase activity is usually within normal limits. Cope and Churchill^{18, 19} and Albright and coworkers¹² have shown that the higher the phosphatase activity preoperatively the greater is the possibility of tetany after complete removal of an adenoma or subtotal removal of hyperplastic tissue. No correlation exists, however, between the height of the serum calcium and the probability of tetany. Thus if the preoperative phosphatase determination is high, postoperative tetany should be looked for and treated as soon as premonitory symptoms develop.

Pathology—The total weight of the normal parathyroid glands is 0.11 to 0.13 gm. There are usually four glands but as few as two and as many as six have been found in a given subject. The glands are composed of four kinds of cells: the chief or principal cell, the "wasserhelle" cell, the pale oxyphil cell, and the dark oxyphil cell.

The pathology of the parathyroid tumors has been worked out by Castleman and Mallory.⁶ "It was found possible to divide the cases sharply into two groups: one of them characterized by diffuse uniform changes throughout all the glandular tissue—an obvious hyperplastic process—the second by a proliferative area limited to one gland, frequently even to a portion of it, or rarely involving parts of two glands—neoplasia." Seven of seventy cases reported by Cope⁵ were examples of diffuse hyperplasia of the water-clear cells. Patient IV reported above had primary hyperplasia of the wasserhelle cell type. It is noteworthy that this was not recognized at the first operation making a second operation necessary. The pathologic condition now recognized as primary hyperplasia, usually of the wasserhelle cells, is extremely important in that failure to recognize it will account for failure to correct the disease. Two adenomas of chief cell type may occur in the same patient and may account for residual disease after removal of a single adenoma.¹⁸

Adenomas usually weigh from 0.5 to 20 gm. but one weighing 101 grams²⁰ has been reported. They are composed predominantly of chief cells but in rare instances oxyphil cells predominate. Rosette formation and pseudoglandular appearance, as in Case VI, occurs in some cases. Gentile and associates²¹ reported a case with typical symptoms of hyperparathyroidism caused by a malignant parathyroid tumor which metastasized locally, resulting in recurrence of symptoms cor

rected by a second operation. Many malignant parathyroid tumors without hyperparathyroidism have been reported.

Secondary hyperplasia of the parathyroid glands occurs in renal insufficiency, in rickets, Paget's disease, osteomalacia and occasional instances of metastatic cancer of the bones. This hyperplasia is characterized by a predominance of chief cells in contradistinction of the predominance of wasserhelle cells in primary hyperplasia.

Differential Diagnosis.—Of course many bone diseases have to be considered in the differential diagnosis of hyperparathyroidism with skeletal involvement. *Paget's disease* is never generalized. The x-ray appearance is diagnostic, there is no disturbance of serum calcium and inorganic phosphorus concentrations, but there usually is considerable increase in serum phosphatase. *Multiple myeloma* may be generalized but the x-ray appearance is usually diagnostic. The phosphatase is usually normal and serum inorganic phosphorus is normal. Hypercalcemia and hypercalciuria may occur rarely. In addition there is often hyperglobulinemia so that the erythrocyte sedimentation rate is very rapid and excessive rouleau formation is noted (so-called "greasy blood smear"). Bence-Jones protein is present in the urine of a majority of patients. Generalized *cancer metastases* to bone rarely cause generalized decalcification. The serum inorganic phosphorus is almost always normal even though the calcium may be increased. Histological evidence of metastases may be the only diagnostic feature, but usually the x-ray appearance and clinical features suffice to differentiate this bone disease from the others. *Hyperthyroidism* offers a special problem in that nervousness and irritability are common to both diseases. The skeleton may be very extensively decalcified. The serum inorganic phosphorus is normal, the phosphatase is normal or very slightly elevated and of course calcium excretion in the urine usually is considerably increased. Of course the usual evidence of hyperthyroidism is very important. *Lipoid granulomatosis*, i.e. Hand-Schüller-Christian disease can be differentiated readily by x-ray examination. *Osteomalacia* and *renal osteodystrophy* have characteristic biochemical findings. A condition variously named *osteitis fibrosa cystica disseminata*, fibrous dysplasia of bone, and Albright's disease has caused much confusion and has led to erroneous diagnoses of hyperparathyroidism. This disease is characterized by brown spots (café au lait spots) on the body, soft tissue tumors (neurofibromata) occasionally precocious puberty in females and involvement of any part of the skeleton often just on one side of the body but never generalized. It is a variant of neurofibromatosis. An excellent review of this disease has recently been provided by Thannhauser.⁷

Treatment.—*Surgery.*—The principles and technic of surgery of the parathyroids have been thoroughly discussed by Cope and Churchill¹⁰ and the reader is referred to their papers. The preoperative diagnosis must be firmly established for in this disease the diagnosis

cannot be excluded by a single exploratory operation. The surgeon should be thoroughly convinced of the accuracy of the diagnosis. The most meticulous and thorough dissection is necessary in order to find small adenomas and, more important still, in order to identify and not interfere with normal parathyroid tissue. Cope has discussed the practical relations of embryology of the glands to possible aberrant positions. Sixteen out of sixty patients had tumors in the anterior or posterior mediastinum. Four out of fifty-four had two adenomas. When one fails to find a tumor or hyperplasia in the neck region, the posterior superior mediastinum can be explored from the neck, but when this fails also, a second operation with reflection of the upper part of the sternum for exploration of the anterior mediastinum must be carried out. Subtotal resection of a solitary adenoma is recommended if no normal parathyroid tissue is recognized or if there is a very high phosphatase and renal insufficiency. It is extremely important to have rapidly frozen sections and histologic examination of any tissue removed at operation to identify it as parathyroid tissue and also to detect primary hyperplasia.

Oliguria and retention of nonprotein nitrogenous products may be serious complications in the immediate postoperative period. During the operation the administration of 5 per cent glucose solution in distilled water intravenously by constant drip and after the operation the administration of 3000 cc or more of fluids per day, parenterally as necessary, are important measures in preventing oliguria. Calcium salts for intravenous use should be available for prompt administration to alleviate tetany if it is severe.

Prevention of Tetany—The surgical principles and technic outlined by Cope and Churchill were followed in most of the present cases but in Cases I and VI total resections were carried out even though tetany was to be expected. Normal parathyroids were identified in each instance. Particularly in Case VI expectation of the development of tetany was great and, to be sure, he did develop mild tetany on the seventh day, but he was carefully watched and vigorously treated from the onset. In Case I the mild symptoms of tetany were easily controlled by the administration of 1.25 mg of dihydrotachysterol and 6 gm of calcium lactate orally each day for one month. Patient VI received dihydrotachysterol continuously from the day immediately before surgery in a dose of 3.75 mg per day for the first month. Then the dose was reduced to 1.25 mg per day. Calcium lactate in doses ranging from 6 to 24 gm per day was also given orally. It was necessary to administer calcium gluconate intravenously on three occasions for the control of minor tetanic symptoms. Because of the calcemic effect vitamin D₂ could be used in large doses (from 100,000 to 400,000 units a day) to as good advantage for it has been demonstrated that such doses are just as effective as dihydrotachysterol.²² It is suggested that prophylactic administration of either substance together with cal-

cium salts, from the day of or the day following surgery until the danger of tetany is passed, may prove to be of definite benefit in preventing or minimizing tetany postoperatively. The use of the Sulkowitch test at frequent intervals is of much assistance in anticipating the onset of tetany and in judging a safe dose of the drug, complete absence of a precipitate indicates serum calcium of 8 mg per 100 cc. or lower and a heavy precipitate indicates high calcium levels. If a tumor is not found at operation no harm can be done by a single or even several doses of dihydrotachysterol and the drug can be discontinued.

Follow-up Program—A follow-up of every patient for a number of years is necessary to be sure that recovery has occurred or that recurrence does not go on untreated. It is difficult to define an adequate follow-up program, but certainly the main features of the biochemical syndrome should be checked every three months for a year and then every six months for a while. X-rays of the skeleton should be taken according to the symptoms and other progress. The first patient has been lost sight of and the fourth patient has failed to return at the appointed interval, so that our own follow-up has not been ideal.

Improvement of the skeleton can be attained without surgery by the administration of large amounts of calcium, but such treatment has resulted in further renal damage and certainly should not be pursued. X-ray treatment of the region of the neck has been without avail in carefully studied cases and should be abandoned as a form of treatment, for it can only delay adequate surgical treatment and delay may be costly, particularly as far as the kidneys are concerned.

SUMMARY

Six cases of hyperparathyroidism are described. Many of the problems, some of the pitfalls, most of the symptoms, and the major pathologic groups of the disease have been encountered. Stress has been placed on the symptomatology referable to the skeletal and the genitourinary systems as the most important clue to diagnosis. Polyuria as a single symptom was the initial clue in two patients who had been diagnostic problems at this and other hospitals and clinics. The biochemical findings in each case were diagnostic. Osteitis fibrosa cystica generalisata was present in five cases. One patient has osteoporosis comparable in severity to that which could be expected normally at her age, furthermore, the phosphatase activity of her serum was normal. A method of prophylaxis or amelioration of postoperative tetany has been suggested and tried in several patients, and should be given further trial. The use of the Sulkowitch test at frequent intervals to anticipate hypocalcemia and tetany in the postoperative period has been found to be very valuable.

THE RESTRICTION OF ACTIVITY IN CORONARY OCCLUSION WITH PARTICULAR REFERENCE TO THE EXTENT OF MYOCARDIAL INFARCTION

G N AAGAARD, M D.,* AND C. J. WATSON, M D, F A C.P †

CORONARY occlusion commonly results in myocardial infarction. The classical clinical picture of agonizing substernal pain often radiating down the arms, ashen color, cold and clammy skin, reduced blood pressure, soft and muffled heart tones is well known and requires no further comment. Also well known are the common objective or collateral findings of myocardial infarction which include the following fever, leukocytosis, increased sedimentation rate, pericardial friction rub, and the characteristic electrocardiographic changes. In addition to these, attention has been called in recent years to the frequent finding of increased amounts of urobilinogen in the urine.^{1 2}

It has been established that coronary occlusion does not always cause myocardial infarction. Blumgart and his co-workers³ have shown in clinical and pathological studies, that one or more of the major coronary arteries may be occluded without gross or microscopic evidence of myocardial infarction at postmortem examination. Review of the histories often failed to reveal either previous angina of effort or attacks of chest pain resembling those usually associated with myocardial infarction. Blumgart believes that sufficient collateral circulation was present at the time that complete closure occurred to maintain an adequate blood supply and prevent infarction.

It is evident that coronary occlusion may be a serious event leading to myocardial infarction and death on the one hand, or a relatively benign episode with little or no infarction, and at times with little or no distress. Between these two extremes, there are a large number of cases in which the presence of an infarct is doubtful.

Since the amount of damage suffered by the myocardium following coronary occlusion may vary so markedly from case to case, it is obvious that no single plan of management is applicable in all cases. Restriction of activity is one of the major means employed in the treatment of coronary occlusion, hence the question often arises as to how much and how long the activity of the patient should be restricted. Strict bed rest for one to two months with as complete restriction of

From the Department of Medicine, University of Minnesota Hospitals, Minneapolis, Minnesota

* Instructor in Medicine, University of Minnesota.

† Professor and Head Department of Medicine, University of Minnesota.

activity as possible for the first two weeks has been a common practice in the management of such cases. Recently Harrison⁴ and Levine⁵ have emphasized the fact that bed rest may actually be harmful to patients with cardiovascular disease if it is excessively prolonged.

The following cases of coronary occlusion illustrate some of its varying manifestations and afford an opportunity to consider its management from the standpoint of the presence or absence of an infarct.

CORONARY OCCLUSION WITH CONCLUSIVE COLLATERAL EVIDENCE OF MYOCARDIAL INFARCTION

CASE I—M P, a 51 year old white woman, suffered an attack of substernal pain with radiation to both arms on November 2, 1944. The pain lasted several hours and then disappeared. It returned on November 4 and continued for two days when she was admitted to her local hospital. The pain continued despite bed rest. Temporary relief was obtained from nitroglycerin administered under the tongue. Because of the persistent pain she was admitted to the University of Minnesota Hospitals on November 11, 1944. Inquiry into her past health revealed that she had been found to have hypertension several years previously. Dyspnea and angina on effort had been present for several years.

Physical examination revealed the following pertinent findings: blood pressure 170/120, pulse 120 per minute, rhythm regular, temperature 99.6° F, lungs clear, heart tones soft, tic-tac rhythm. The temperature rose to 101° F on the day after admission and remained moderately elevated until November 20 when it became normal consistently.

The white blood count on admission was 24,250. The blood sedimentation rate (Westergren) recorded in millimeters in one hour was 65 on November 13, 93 on November 16, and 90 mm on November 21. The 2 to 4 P.M. urine Ehrlich value* was 5.4 units on November 13 and had fallen to 1.8 EU on November 19. The electrocardiogram taken on November 11 (Fig 81A) was characteristic of posterior myocardial infarction. A pericardial friction rub was heard over the cardiac apex on the second hospital day. Her condition was serious for several days. She then improved and was symptom free on November 20, 1944.

Comment—This case exhibits the characteristic picture of coronary occlusion with myocardial infarction. All of the objective signs of infarction are present in significant degree. The magnitude of the leukocytosis, the prolonged serious state of the patient, and the widespread friction rub with a posterior myocardial infarction suggest that the infarcted area is large. Mallory⁶ has shown that small infarcts may heal completely in five weeks but that large infarcts may take up to two months. This patient should be kept at absolute bed rest for two or three weeks and in bed for six to eight weeks. Only then should she be permitted to be up for short, increasing periods. If such activity is well tolerated, she may be permitted to walk about her room and then very gradually widen the sphere of her activities.

* This is simply a quantitative measure of the urine Ehrlich reaction. Since this is chiefly due to urobilinogen, the values obtained are roughly correlated with the actual content of urobilinogen.⁷ One Ehrlich unit is the amount of color produced in the Ehrlich reaction by 1 mg of crystalline urobilinogen. The upper limit of normal for the 2 to 4 P.M. urine sample probably should not exceed one unit.⁷

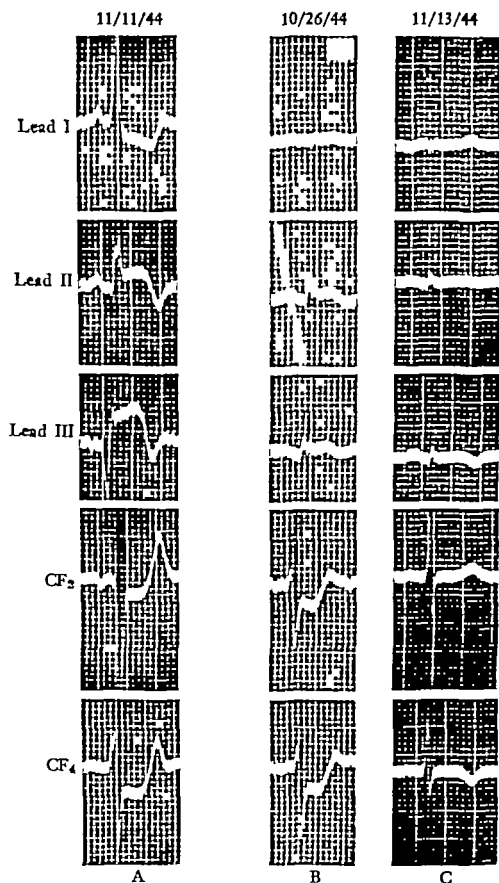

Fig 81—A, Electrocardiographic changes in Case I B, C, Electrocardiographic changes in Case II.

CORONARY OCCLUSION WITH MINOR OR QUESTIONABLE EVIDENCE OF INFARCTION

CASE II—M B., an 87 year old white woman awakened at 6 30 A.M. on October 27 1944 with marked dyspnea but no precordial pain. She had noticed slight dyspnea and palpitation on climbing stairs. She had never noted angina on effort.

Physical examination revealed the following pertinent findings. The patient was extremely dyspneic. Blood pressure was 110/70 and pulse 120 per minute. Bubbling râles were heard throughout the lungs. Heart tones were soft. Temperature was normal except for the third day when it rose briefly to 99.8° F.

The white blood cell count was below 10,000 except for a count of 11,350 per cu mm on October 29. At this time the neutrophils were 72 per cent. Sedimentation rate varied but slightly, being 29 mm in one hour on October 27 and going up to maximum value of 37 mm on November 11. The daily urine Ehrlich reaction was normal for seventeen days after the attack. An electrocardiogram on October 27 (Fig 81, B) showed changes typical of posterior myocardial infarction. Serial electrocardiograms showed progressive changes until November 13 (Fig 81, C), after which date no further changes occurred.

The patient obtained prompt relief from the initial dyspnea following $\frac{1}{8}$ grain of morphine sulfate hypodermically. She was placed in an oxygen tent for two days and had no recurrence of symptoms. She was allowed to be up on the nineteenth day, and her activity was gradually increased. On January 25, 1945, she was feeling quite as well as prior to the attack.

Comment—This case presents several points which are worthy of mention. At no time did the patient complain of chest pain. Her attack was signaled by the sudden onset of symptoms of left heart failure. In this connection it may be noted that numerous cases of painless myocardial infarction have been recorded^{8, 9, 10, 11, 12}. Atypical manifestations which are reported include sudden onset of dyspnea, cough or edema, sudden changes in cardiac rhythm, collapse or fainting, nausea and vomiting, central nervous system complaints, including vertigo, psychic disturbances, hemiparesis or coma. Although this case exhibited typical electrocardiographic findings of myocardial infarction, there was but very little other collateral evidence of necrosis of heart muscle. The symptoms were of very short duration, the temperature was elevated but once on the four-hour record, leukocytosis was minimal, and the sedimentation rate rose but insignificantly above the level shown shortly after the initial symptoms. Because of her age and the evidence which suggests that the infarct, if any, is small, the patient's activity should not be restricted too greatly nor too long.

CASE III—J J, a 56 year old white woman, noted the onset of substernal pain while sitting in church on November 12, 1944. She felt weak and noted profuse perspiration. The pain persisted until the following day, when she was admitted to the University of Minnesota Hospitals. She had first been told that she had hypertension two years previously. Exertional dyspnea and orthopnea had been present for several years. Angina on effort relieved by rest had been present for two years.

Physical examination revealed the following pertinent findings: blood pressure 200/98, pulse 70 per minute, temperature 98° F. Ocular fundi: A-V compression and moderate narrowing of the arterioles. The lungs were clear and heart tones were normal, but a soft systolic murmur was heard along the left sternal border. The temperature remained normal throughout.

The daily leukocyte count was never above 7600 per cu mm with uniformly normal differential counts. Sedimentation rate was as follows: November 13, 36 mm, November 17, 30 mm, November 20, 13 mm. The Ehrlich reaction of the

urine was normal on November 14, increased to 3.38 units two days later and had decreased to 1.8 units on November 20. An electrocardiogram on November 14 (Fig 8⁷ A) revealed a negative T wave in Leads I and II and in the pre

Fig 82—A, B, C, Electrocardiographic changes in Case III.

cordial leads, CF₂, and CF₄. There was no elevation of S-T. On the following day there was a slight change in the ST-T portion in CF₂ (Fig 82 B). On November 20, 1944, T had become upright in Leads II and CF₂ (Fig 8⁷ C).

Comment—This patient also shows some of the objective evidence of myocardial infarction. Note the absence of fever and leukocytosis. Levy and his co-workers¹⁸ found fever at some time during the course of cardiac infarction in 100 per cent of the cases they studied. The increased excretion of urobilinogen and the changing electrocardiogram are significant. It is difficult to evaluate the sedimentation rate in this case since it was slightly elevated on November 13, the day after the onset of symptoms. This is earlier than the peak usually occurs and suggests that this may not be due to the coronary occlusion. The absence of some of the collateral evidence of infarction suggests that the infarct is a small one. Such a patient can probably be safely lifted into a chair after the second week, especially if she tolerates poorly confinement to bed. Walking about the room can probably be permitted with relative safety during the fourth or fifth week.

CASE IV—C S., a 67 year old white man, was admitted to the University of Minnesota Hospitals on December 7, 1937. He had suffered substernal pain on effort, after meals and emotional stress, for two and one-half years. The attacks had become more frequent and were precipitated by very slight exertion. Rest and nitroglycerin gave relief. He was admitted to the hospital to see if anything more could be done to prevent these attacks.

Physical examination revealed the following pertinent findings: blood pressure was 140/90, and the pulse 80 per minute. The lungs were clear. Heart tones were normal, and no murmurs were heard.

The electrocardiogram (Fig 83, A) showed left axis deviation, widening and slurring or notching of QRS and what appears at first glance to be a Q wave in Lead III. There is, however, a small R wave preceding the downward deflection so it should probably be regarded as an S wave. It should be noted that the fourth lead in the electrocardiograms in this series was taken with the older technic in which the initial QRS deflection and the T wave are normally downward. Sedimentation rate was 18 mm in one hour. At 7:30 A.M., on the day after admission the patient suddenly collapsed in the bath tub and did not respond. Involuntary defecation occurred. The skin was cold and clammy and the blood pressure 120/64. Aminophylline, grains $3\frac{3}{4}$, was given intravenously. Shortly afterwards the patient responded normally, and normal color and skin temperature returned. An electrocardiogram (Fig 83, B) taken one hour after the episode shows elevation of S-T in Leads III and IV with T_3 positive instead of negative in the previous tracing. Depression of S-T in Leads I and II is also seen. A third tracing (Fig 83, C) taken three hours later reveals that these changes have disappeared and shows no significant variation from the first record. Tracings made on the next three days showed no change from the control record. An electrocardiogram taken December 13 showed elevation of S-T only in Lead IV. It is possible that this was taken during an episode of angina, but no definite information is available regarding that point.

Temperature and daily leukocyte counts remained normal. Urine urobilinogen was normal each day. The sedimentation rate varied from 8 to 20 mm in one hour except for a reading on December 10 when a value of 31 mm was obtained. The patient's condition remained the same as on entry, anginal attacks occurred after meals, on exertion, and after emotional stress related to telephone calls. Relief was obtained from nitroglycerin.

The patient was discharged from the hospital on December 18, 1937, at 3 P.M., feeling very well. That evening he became excited while making arrangements

to catch a train and had severe substernal pain. He was readmitted to the University Hospital at 10 P.M. He was restless and apprehensive, with a blood pressure of 130/90, pulse 120, and respiration 30 per minute. An electrocardiogram (Fig 83, D) taken after his readmission shows a rate of 136 per minute and

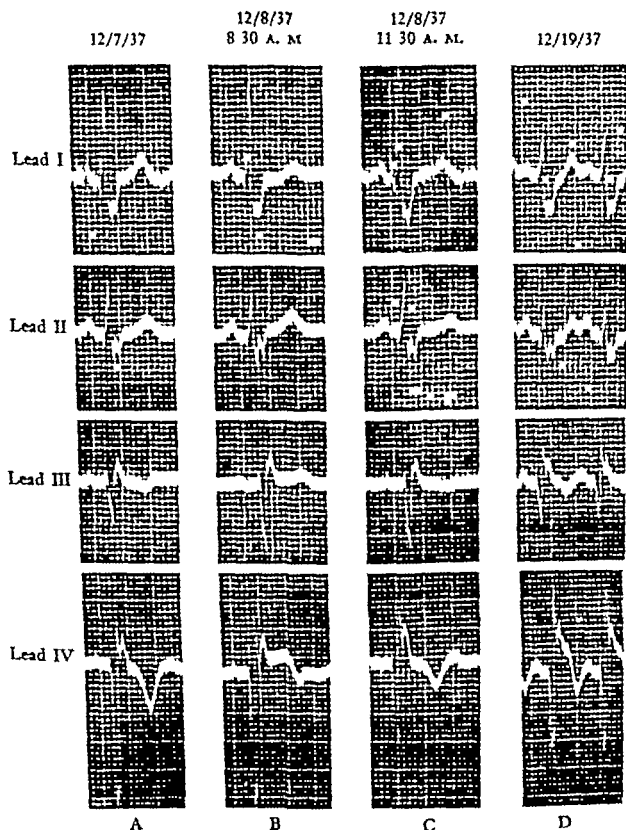

Fig 83—A, B, C, D, Electrocardiographic changes in Case IV

changes of S-T and T portions similar to that in Fig 83 B. The white blood cell count on December 19 was 14,200 per cu. mm. Despite complete bed rest and other therapeutic measures, the patient expired at 4 P.M. on December 19, 1937. Unfortunately permission for necropsy was denied.

Comment—The episode of unconsciousness and collapse noted above may represent another example of an atypical manifestation of coronary occlusion. The electrocardiogram shows changes suggestive of posterior myocardial infarction but these are very transient and disappear in three hours. Whether such electrocardiographic changes are due to myocardial infarction (necrosis) or to temporary myocardial ischemia without infarction is an important question. That myocardial ischemia produced by exercise or breathing a mixture of 10 per cent oxygen and 90 per cent nitrogen may cause S-T depression and T wave inversion is well known^{14 15}. Less commonly, this may produce the Q-T pattern with S-T deviation usually considered typical of myocardial infarction¹⁶. The differentiation between myocardial infarction and temporary coronary insufficiency cannot be made by a single tracing. The length of time that the electrocardiographic changes are present is of value. If the pattern disappears and the tracing returns to the control pattern present before the attack within a period of forty-eight hours or less, the diagnosis of transitory myocardial ischemia is more likely. Collateral evidence of infarction must be sought. In this case none was present with the possible exception of the slight change in the sedimentation rate.

In retrospect, it is thought that somewhat more attention might have been given in this case to the changing electrocardiographic pattern, and the slight increase in sedimentation velocity. An autopsy was not permitted so no definite information is available as to the actual course of events. It is believed likely, however, that the patient suffered a new coronary occlusion on the day before death, and that the result would probably have been the same even if activity had been more restricted.

CORONARY OCCLUSION WITHOUT MYOCARDIAL INFARCTION

Blumgart and Schlesinger's studies have shown that coronary occlusion occurs not infrequently without resultant myocardial infarction. The importance of recognizing such an event when it occurs is obvious. During the period immediately following coronary occlusion, the degree of myocardial ischemia which results will depend on the amount of blood available through the preexisting collateral circulation, and the demand of the myocardium for oxygen which depends, of course, in large measure upon the activity of the patient. In experimental occlusion of the coronary arteries in dogs, it has been demonstrated that collateral circulation develops relatively slowly as compared with that developing after occlusion of such vessels as the femoral or carotid arteries¹⁷. A week or more may be required for adequate retrograde flow to develop in the dog's coronary arteries. Although such work cannot perhaps be applied directly to the problem in humans, it is likely that the development of coronary collateral circulation is even slower in man, as is evident from the slower rate of healing of infarcts in man as compared with dogs.⁶

It is obvious that the diagnosis of coronary occlusion without myocardial infarction cannot be proved during life. This would require a blind faith in the lack of collateral evidence of infarction, such as already referred to. While it is believed that in the absence of such evidence the presence of an infarct may be seriously doubted, it is recognized that further clinical and pathologic correlations are needed before one can employ this collateral evidence in an absolute manner.

The diagnosis of recent coronary occlusion without infarction must be considered under the following circumstances: (1) prolonged substernal pain characteristic of coronary occlusion without ensuing collateral evidence of infarction, (2) the *sudden* or *rapid* onset of the typical syndrome of angina pectoris, i.e., pain on effort, emotional stress, or after meals, or of symptoms of congestive heart failure, nausea and vomiting, syncope, collapse, and the central nervous manifestations noted above without any other satisfactory explanation, (3) sudden or rapid increase in the frequency or severity of anginal attacks in a patient who has previously suffered with angina pectoris. Any of these clinical pictures should suggest the possibility of coronary occlusion.

CASE V—E. H., a 55 year old white woman, had enjoyed good health until July 11, 1940, at 1:30 P.M., when she suddenly experienced an attack of severe, viselike pain in the substernal area. There was some radiation to the interscapular area. With the pain she noted dyspnea, orthopnea, faintness, and a sense of impending death. She vomited once without relief from the pain. When she was seen at her home two hours after the onset, the pain was still very intense. Physical examination revealed the following pertinent findings: the patient was obviously in acute distress, the skin had an ashen pallor with slight but definite cyanosis of the lips and extremities. Blood pressure was 110/90, and pulse 58 per minute and of poor quality. Heart rhythm was regular. Cardiac tones were muffled and distant.

The patient was admitted to the University of Minnesota Hospitals by ambulance a few hours after the onset. An electrocardiogram showed a small Q wave in Lead III; there was no displacement of the S-T junction and the T waves were upright in all four leads. Morphine sulfate was given subcutaneously when the patient was seen at home and provided relief from this pain. Because of cyanosis, the patient was placed in an oxygen tent immediately after her entry to the hospital ward. Her color improved immediately and she did not complain of further pain during her hospital stay.

The patient's temperature was consistently normal save for one recording of 99° F. on the fourth day of her illness. The white blood cell count was 5000 and 6000 per cu. mm. on two occasions. Sedimentation rate was 12 mm. in one hour on the fourth hospital day. Ehrlich reactions of the urine, unfortunately, were not recorded. A second electrocardiogram showed no change from the original tracing.

The patient was completely free of symptoms after the first few hours of her hospital stay and was discharged from the hospital on July 15, 1940, the fourth day after the attack, with instructions to limit her activities at home. Attempts to obtain further information about this patient were unsuccessful.

Comment—Although exact proof of coronary occlusion is lacking, the onset and character of the attack was most suggestive. The absence of any history of gastrointestinal complaints, pulmonary disease, etc., is of additional help in making a presumptive diagnosis of coronary occlusion. The absence of collateral evidence of myocardial infarction supports the view that this is an instance of coronary occlusion without infarction. No one could deny that coronary spasm might produce such a clinical picture, although it would seem wiser, here, to make a diagnosis of occlusion without infarction and treat the case as one of coronary occlusion. Ten days to two weeks of bed rest followed by a similar period of confinement in one room or at least on one floor, is believed advisable in such instances. This would give time for additional collateral circulation to develop under optimal conditions of rest for the heart.

CASE VI—E. B., a 53 year old white man, was admitted to the University of Minnesota Hospitals on November 23, 1939. He stated that five years previously he had had a sudden attack of oppressive pain in the precordial and substernal areas, with radiation down his left arm. The pain had lasted several hours and he felt so weak and incapacitated that he had stayed home from work for several days but had not called a doctor to see him. Following this he had noted that exertion which had formerly caused no distress now caused dyspnea. In fact, because of this shortness of breath, he had found it necessary to give up golf.

On the day before admission, while driving his car in the evening, the patient noted the sudden onset of substernal pain similar to that described above. He was able to drive home by himself. The pain lasted four hours and was not relieved by an enema. He went to work on the morning of admission, but while at his desk he noted the sudden onset of substernal soreness and heaviness and felt as if he would collapse. A doctor was called and the patient was taken to the hospital.

Examination at the time of admission revealed the following pertinent findings. Patient was pale, and slight cyanosis of the lips was present. Blood pressure was 110/90 and pulse 60 per minute, weak and regular. Heart tones were soft and distant. No murmurs were heard. Crepitant râles were present at both bases of the lungs posteriorly. An electrocardiogram was taken on admission and was normal. White blood cell count was 8600.

During his four-day hospital stay, the patient's temperature was always normal. Treatment consisted of aminophylline 0.5 gm given intravenously at the time of entry, and sedation. His substernal discomfort disappeared after he had been in the hospital a few hours. This patient had no further pain or dyspnea during a subsequent two-year period.

Comment—It is entirely possible that this patient had an occlusion of one of his coronary arteries in the attack which occurred five years before he was observed in this hospital. The diagnosis of coronary occlusion without myocardial infarction for the present admission is probably justified because of the characteristic subjective manifestations and the lack of collateral evidence of infarction, although this was not studied in as much detail as is desirable. In this case also, it would perhaps have been better to err on the side of greater restriction of activity for a longer period.

CASE VII—R. H., a 48 year old white man, was first seen in the Out Patient Department of the University of Minnesota Hospitals on July 23 1941. He stated that he had enjoyed good health and normal activities until exactly two weeks previously. On that day he had noticed that walking up a small hill which he climbed each day on his way to the streetcar caused an oppressive type of pain in the substernal area. He also noted for the first time on that same day that climbing stairs also caused the same type of distress. The discomfort would disappear if he remained absolutely quiet for five minutes as soon as the pain appeared.

Examination ten days after the onset of angina showed nothing of significance. The blood pressure was 134/84. The heart was normal in size and contour and no murmurs or abnormal sounds were heard. The pulse was 86 per minute and regular. Fluoroscopy confirmed the finding that the heart was normal in size and showed nothing else of significance. An electrocardiogram was within normal limits. The leukocyte count and temperature were normal. Nitroglycerin, grain 1/100 when given under the tongue gave relief from the symptoms. The patient remained at home for two weeks during which time he did not climb stairs or engage in anything but the mildest activity. At the end of that time he was able to engage in his normal activities again without distress. It was possible to follow this patient for one year during which he complained of nothing more than mild dyspnea on exertion.

Comment—Again no proof can be offered as to the exact diagnosis. The sudden onset of angina of effort in a patient previously free of cardiac symptoms suggests reduced coronary flow. In the absence of other causes of myocardial ischemia such as acute anemia, shock, tachycardia, and severe toxic states, a presumptive diagnosis of coronary occlusion without myocardial infarction is in order. Without causing undue alarm, the patient's cooperation should be obtained in a program of moderate restriction of activity.

SUMMARY AND CONCLUSIONS

1 Collateral evidence of myocardial infarction should be sought in all instances where the diagnosis of coronary occlusion is entertained. This evidence includes the following: (a) fever, (b) leukocytosis, (c) increased sedimentation velocity and (d) increased Ehrlich reaction in the urine (urobilinogen). Serial electrocardiographic changes are, of course, of the utmost importance, but it is believed that changes may occur in some cases without actual necrosis of heart muscle.

2 In instances where conclusive collateral evidence of infarction is obtained, bed rest is advisable for at least six weeks. Where such evidence is lacking or questionable, it is believed that restricted activity out of bed may be permitted after a shorter period of time. This assumes that a daily search for the collateral evidence has been made for two weeks following the attack.

RECENT ADVANCES IN PHARMACOLOGY

EDGAR W. WARREN, M.D.,* AND THOMAS FINDLEY, M.D., F.A.C.P.†

ANY review such as this must necessarily be incomplete. In the present instance, omission of a discussion of the sulfonamides and penicillin is intentional for obvious reasons. The vitamins have also not been included for they are much talked about, and we have not felt qualified to write about the remedies for tropical diseases. The unintentional omissions are due to ignorance and neglect, in self-defense it should be stated that the most important announcements are often made from obscure sources. We have tried to make this review of immediate use to the practitioner.

CENTRAL NERVOUS SYSTEM

Demerol—Since 1939 intensive studies¹⁻⁷ have been made on the pharmacologic and clinical properties of the ethyl ester of 1-methyl-4-phenyl-piperidine-4-carboxylic acid (demerol), a synthetic product related to morphine and atropine. It combines the analgesic effects of the former drug with the spasmolytic actions of the latter.

Clinically,⁸⁻¹⁷ demerol is useful in relieving conditions accompanied by *smooth muscle spasm*—biliary or ureteral colic, bronchial asthma, abdominal cramps, angina pectoris, arterial thrombosis or embolism, labor pains and hiccups. The effect of 100 mg. of demerol on the pain perception threshold is roughly equivalent to that produced by 15 mg. of morphine sulfate.¹⁸

Side reactions of a moderate degree occur in about 25 per cent of bed patients, but giddiness, pallor, sweating, blurring of vision and nausea develop in 50 per cent of ambulatory patients. This drug has been recommended,¹¹ therefore, mainly for bedridden patients in doses of 50 to 100 mg. every three to four hours although much larger doses have been safely given. It is more effective when given intramuscularly although the rapidity of action after oral administration is but slightly delayed. It should never be given intravenously.

*Toxic effects*⁸ may simulate poisoning by atropine or morphine. Thus, there may be extreme mydriasis, dryness of the mouth, tachycardia, hallucinations, disorientation, muscular twitching and occasionally slight rise in blood pressure, pulse rate and temperature. Comparable to any drug capable of producing euphoria, demerol may induce

From the Division of Internal Medicine, Ochsner Clinic and the Department of Medicine, Tulane University School of Medicine, New Orleans.

Assistant in Division of Internal Medicine, Ochsner Clinic. Instructor in Medicine, Tulane University School of Medicine.

†Director, Division of Internal Medicine, Ochsner Clinic. Assistant Professor of Clinical Medicine, Tulane University School of Medicine.

addiction, although the tendency is much less than that of morphine^{8 10, 20, 21} It has been clearly shown²² that on withdrawal of the drug after thirty to sixty days' usage, the usual symptoms of yawning, lacrimation, rhinorrhea, sweating, dilated pupils, insomnia and aching legs may rapidly appear

In the search for morphine substitutes, Jones and Chapman²³ have reported recently on the comparative analgesic effect of morphine sulfate and *monoacetylmorphine* They felt that a given dose of the latter was four times as effective as a similar dose of morphine sulfate—not only regarding the maximum threshold to pain but also as to duration of action Further, monoacetylmorphine produced less toxic reactions such as nausea and vomiting However, euphoria of moderate degree was also more frequently noted They suggest that these two actions unfortunately may lead to more frequent addiction

Barbiturates—The most important extension of the use of the barbiturates has been in relation to *war casualties of a psychiatric nature*^{24 25} Properly employed as one feature of a highly specialized technic, the drug seems to release cortical inhibitions and permits mental catharsis Soluble pentothal sodium has also been advocated²⁶ for the control of neurogenic hyperthermia which follows injury to the hypothalamus

Toxic reactions continue to occur In a case of exfoliative dermatitis the daily administration of 500 mg of nicotinic acid seemed efficacious²⁷ The treatment of respiratory failure with such analeptics as picrotoxin, metrazol and coramine has been recently reviewed by Hazelton²⁸ After all these measures had failed in one case, sodium succinate (22 gm in a 10 per cent solution) was administered intravenously over a period of five hours with recovery²⁹

Motion Sickness—For obvious reasons much interest has naturally centered about the prevention and treatment of seasickness and airsickness For the prevention of the former, a careful study³⁰ has suggested that *hyoscine* in oral doses of 0.6 mg is more effective than any other drug It produced some dryness of the mouth, diminution of sweating and elevation of body temperature, but apparently had no effect on infantry marksmanship It is contraindicated in cases in which heat stroke might develop *Benzedrine* has also been advocated for the prevention of motion sickness

Epilepsy—Waelsch and Price³¹ report on the effectiveness of *glutamic acid* in the treatment of petit mal and other epileptic equivalents It was originally thought that the efficacy of the drug was due to its capacity for producing acidosis but these workers have apparently abandoned that idea and now suggest that amino acid deficiency may influence cortical activity This drug apparently does not influence gross seizures but is effective in controlling those episodes associated with slow wave activity in the electroencephalogram Given in doses of 12 gm daily it was well tolerated, seemed to increase the vigor of the patients and produced considerable reduction in the psychomotor seizures

LOCAL ANESTHESIA

Procaine Hydrochloride—Continued efforts have been made to find a less toxic regional anesthetic than procaine. An isomer of the latter, *monocaine*, has been synthesized and found³² to be equal in efficacy and toxicity, though slightly more irritating to the local tissues. *Monocaine* has the advantage of being more stable at room temperature and to light. At first *monocaine* was thought to have a greater pressor action but this has been disproved, nor does it potentiate the action of epinephrine. Other related drugs, such as octocaine and eucupin have also been brought forward but with no convincing evidence of their superiority over procaine.

It may not be generally known that procaine is a derivative of *p*-amino-benzoic acid, which inhibits the action of the sulfonamides. It has been clearly shown³³ that procaine will prevent the proper action of sulfonamides in contaminated wounds, as procaine breaks down into *p* amino-benzoic acid. Therefore, the rationale of using mixtures of *sulfonamides* with *procaine* seems erroneous. Recently, it has been suggested³⁴ that procaine be combined with a local antiseptic such as *rivanol*, in the treatment of painful purulent wounds.

The *indications* for the use of procaine have been widely extended. It is commonly used as a temporary or permanent substitute for sympathectomy.³⁵ Local infiltrations are employed in the management of nonarticular rheumatism.³⁶ Paravertebral block is advocated for the treatment of herpes zoster.³⁷ and intercostal injection for the relief of postoperative atelectasis.^{38, 39}

It must be remembered that procaine and its associates are convulsants. Prophylactically therefore, one might very well employ a judicious amount of a barbiturate. Should convulsions occur a calcium salt may be given intravenously. calcium levulinate, gluconate and chloride are decreasingly effective in the order listed. From 3 to 6 cc of per cent sodium is also an effective anticonvulsant. Should syncope occur artificial respiration or the use of 5 per cent carbon dioxide and 95 per cent oxygen is indicated.

Bromsalizol.—Lee, Macht and Picrpont⁴⁰ report that a 4 per cent solution of mono-brom-hydroxyl-benzyl alcohol in peanut oil (*Bromsalizol* Hynson Westcutt & Dunning) produces prolonged paralysis after sympathectomy, an obvious advantage. We have employed it several times, however for injection of the stellate ganglion and have been unable to see that the Horner's syndrome lasted appreciably longer than after the injection of 1 per cent procaine.

AUTONOMIC NERVOUS SYSTEM

Sympathomimetic Drugs—In addition to epinephrine and the familiar ephedrine and amphetamine (benzedrine) several other compounds possessing the ability to mimic stimulation of the sympathetic nervous

system should be mentioned. It is believed that the activity of the pressor amines may be due to their ability to delay or prevent the oxidation of epinephrine, having chemically similar compositions, they may compete with epinephrine for available amine oxidase and thus interfere with its enzymatic destruction. Some of them, however, have special actions which make them clinically useful.

Ephedrine—Kittredge and Brown⁴¹ report the successful treatment of enuresis in a dosage of 50 mg orally at bedtime. They say that even children are not kept awake by this amount.

Neosynephrin Hydrochloride—Differing from epinephrine only in possessing one rather than two hydroxyl groups on the benzene nucleus, neosynephrin is such a stable compound that it raises blood pressure when taken by mouth in doses of about 50 mg. In parenteral doses of 5 mg or less the resulting hypertension may persist for two hours. Like other vasoconstrictors it is contraindicated in shock but is used to sustain blood pressure after the production of spinal anesthesia and has been occasionally useful in orthostatic hypertension. In watery solution or in jelly it is applied topically in the same manner as ephedrine or amphetamine.

Kephrine Hydrochloride—As the hydrochloride, kephrine is used only locally to arrest capillary bleeding. Bandages are impregnated with it and it is also marketed in powder form and as rectal suppositories.

Propadrine Hydrochloride—This drug, closely related to ephedrine, is less likely to cause unpleasant central nervous system stimulation and is regarded as a more potent vasoconstrictor. As a spray or jelly it is used for shrinking nasal mucosa and has recently become popular as a remedy for coryza when taken orally in capsules of 25 or 50 mg.

Racephedrine Hydrochloride (d-1-ephedrine) has the same action, dosage and usage as ordinary ephedrine, which is the levo-isomer. It has no known advantages over the latter drug.

Paredrine (p-hydroxy- α -methyl-phenyl-ethylamine) is closely related to tyramine and amphetamine. It is more stable than epinephrine and possesses a stronger pressor action. It has practically no effect on the central nervous system, gastrointestinal tract or bronchial musculature. In doses ranging from 5 mg intravenously to 50 mg orally it stimulates the myocardium and causes sustained hypertension. These effects have provoked unusual interest because they are apparently unaccompanied by local vasoconstriction or diminished blood flow through the skin. Altschule and Iglauer^{42, 43} found that the drug causes a striking increase in venous pressure. No definite statement can be made but it is possible that the hypertension is caused by a predominant venoconstriction. Paredrine is also a useful mydriatic in dilutions of 1 to 3 per cent.

Paredrinol (veritol, β -[p-oxyphenyl] isopropyl-methylamine) is chemically similar to, but perhaps a little less potent than paredrine, and its actions are probably the same. Stead and Kunkel⁴⁴ thought the pressor action due to (a) constriction of minute peripheral vessels, (b) increased venous pressure or (c) both. Kunkel, Stead and Weiss⁴⁵ found that it could prevent the postural syncope observed in normal persons under the influence of sodium nitrite and thought the drug might be useful in treating those vascular crises caused by diminished muscle tone and the pooling of venous blood. Ranges and Bradley⁴⁶ say that paredrinol may increase venous tone but that its primary action is that of peripheral vasoconstriction.

D-desoxyephedrine Hydrochloride is now receiving attention as a central nervous system stimulant in the treatment of narcolepsy, reactive depression and general fatigue. The literature has been reviewed by Ivy and Goetzl.⁴⁷ Recom-

mended clinical doses (2.5 mg tablets) are smaller than those of benzedrine but no definite advantages have been demonstrated.⁴⁸
Tumaine Sulfate (2-aminoheptane sulfate Lilly) in aqueous solution is used to reduce nasal congestion

Parasympathomimetic Drugs.—*Furmethide*—Furfuryl-thimethyl-ammonium iodide (Furmethide, Smith, Kline and French Laboratories, Inc.) is a parasympathomimetic drug with a strong action on the bladder. Beaser, Lipton and Altschule,⁴⁹ after a careful study of the drug, say that it has certain obvious advantages over mecholyl or doryl for the urologist. In doses adequate to cause contraction of the bladder (approximately 10 mg subcutaneously), it produces sweating, salivation, tachycardia and flushing but little or no effect on blood pressure, the gastrointestinal tract or the bronchial musculature. The oral doses of 30 mg cause only sweating and increased bladder tone. Obviously, the drug should not be used in the presence of obstruction of the neck of the bladder but is claimed to be useful in atonic conditions. It has been used in preference to pilocarpine for demonstrating areas of anhydrosis.⁵⁰

NEUROMUSCULAR APPARATUS

Myasthenia Gravis—The asthenia in this curious disease is due to defective transmission of stimuli from nerve ending to muscle cell. The occasionally remarkable improvement which follows thymectomy forms the basis for a theory which states that a diseased thymus elaborates a curare-like poison. No such secretion has actually been isolated but Wilson and Stoner⁵¹ report that the serum of patients with this disease, unlike that of normal persons, blocks neuromuscular transmission in frog nerve-muscle preparations. Torda and Wolff,⁵² on the other hand, produced evidence which suggests that the fundamental defect consists of inadequate synthesis of acetylcholine, and not in failure of the myoneural apparatus or in abnormal muscle metabolism. In any event, a number of reasonably effective drugs are available for treatment.

Neostigmine is the drug of choice because it prevents cholinesterase from destroying acetylcholine. Viets⁵³ seems to regard myasthenia gravis as a deficiency disease, for he says that neostigmine constitutes a form of substitution therapy. The dosage must be large and should be varied to meet the individual patient's needs from day to day. A tablet of neostigmine bromide (U.S.P.) contains 15 mg and the average daily maintenance dose for 45 ambulatory patients was 163.5 mg some required as much as 375 mg daily. Ephedrine, potassium salts, guanidine and other drugs were regarded as auxiliary measures and not often needed. In severe relapse, neostigmine methylsulfate must be given parenterally. Viets has used as much as 25 mg intramuscularly or 3 mg intravenously in twenty-four hours.
Wilson and Stoner⁵⁴ however, regard ephedrine as a useful adjunct

As much as 50 mg of ephedrine sulfate three times daily may be added to the neostigmine schedule

Bennett and Cash⁵⁵ have pointed out that the intramuscular injection of 1 mg or so of neostigmine methylsulfate as a diagnostic test for myasthenia gravis is reliable in only about two thirds of the cases because it may fail to induce unmistakable increase in muscle power. They think that patients with this disease are abnormally sensitive to curare because their serum contains an excess of curare-like material. Normal persons react only slightly to the intramuscular injection of 0.1 mg for each kilogram of body weight of curare, but patients with myasthenia gravis exhibit definite aggravation of muscle weakness, particularly of the extraocular muscles, after a dosage of one twentieth of this amount. They allow the action to proceed for two or three minutes and terminate it by the intravenous administration of neostigmine (1.5 mg) and atropine sulfate (0.6 mg).

Quinine may also be used as a diagnostic procedure, although the dosage and reliability apparently have not been well established. Harvey⁵⁶ has shown that it accentuates the symptoms of myasthenia gravis and relieves those of myotonia congenita because of its curare-like action. Quinine has been advocated also for the treatment of spasmodic torticollis, myotonia atrophica, paramyoclonus multiplex, the nocturnal leg cramps seen so often in elderly people and other similar conditions.

The rationale for the use of other drugs in myasthenia gravis is perhaps less well understood. *Glycine* has largely been abandoned. *Gumidine*, first advocated by Minot, Dodd and Riven,⁵⁷ has not been shown to have any special advantages. Its mode of action is unknown but it may sensitize skeletal muscles to acetylcholine. *Potassium* has also been used because it is known to facilitate transmission of nerve impulses. If large doses of neostigmine are given parenterally, it is sometimes useful to administer atropine simultaneously in order to eliminate undesirable side effects, the action of acetylcholine on voluntary muscle is not abolished by atropine.

Catalepsy—This paroxysmal inhibition of skeletal muscle, which appears to be initiated by sudden changes in mood, particularly laughter, is related to familial periodic paralysis. Dynes⁵⁸ reports its successful control by the oral administration of *potassium chloride* in doses of about 5 gm daily.

Familial Periodic Paralysis—The concentration of serum potassium is low during the attack and potassium salts cure the weakness.⁵⁹ Wolf⁶⁰ advocates the use of *thyroid*; he makes the astonishing claim that an oral dose of thyroid will alleviate an attack in from ten to thirty minutes and that it is often more effective than potassium.

Fasciculation—Neostigmine in adequate doses will produce coarse fibrillary muscle twitchings in normal persons and in patients with all muscular disorders except myasthenia gravis. Such fibrillations or fasciculations are not abolished by spinal anesthesia or peripheral nerve

block Forster and Alpers⁶¹ review the literature and claim that these abnormal movements originate at the myoneural junction because they are increased by neostigmine, abolished by curare and not exaggerated by acetylcholine.

Other Uses for Neostigmine—Kabat and Knapp⁶² advocate the use of neostigmine for the reduction of muscle spasm in *acute anterior poliomyelitis*. They have shown that this muscle spasm is temporarily relieved by spinal anesthesia and claim that neostigmine acts by inhibiting the spinal cord centers for proprioceptive reflexes. Trommer and Cohen⁶³ have accepted this idea and applied it to the treatment of *rheumatoid arthritis*. They gave 1 or 2 cc. of neostigmine methylsulfate with 0.6 mg. of atropine sulfate subcutaneously three or four times a week, and also gave 15 or 30 mg. of neostigmine bromide three times daily by mouth. This idea should be accepted cautiously because little is known about the action of neostigmine on the spinal cord and one would expect it to increase muscle tone rather than decrease it.

Other Uses for Curare—This material is available under the trade name of Intocostine (E. R. Squibb & Sons). Its use in *tetanus* is not new but Cullen,⁶⁴ who has utilized it recently, claims that the parenteral administration of about 0.1 mg. for each kilogram of body weight will produce muscle relaxation for about three hours. The drug may be given intravenously or intramuscularly. It has also been used to facilitate muscle relaxation during *general anesthesia*. Cullen⁶⁴ and Baird and Adams⁶⁵ have reported favorable results. Pronounced respiratory depression has occurred frequently, however, and the drug has not been generally accepted by general surgeons. It is widely employed for *prevention of fractures during shock therapy* for mental disorders.⁶⁶

HEART AND CIRCULATION

Cardiac Glucosides.—Preparations of digitalis leaf present some obvious disadvantages and the search for satisfactorily pure crystalline glucosides continues. It is not claimed that these present any therapeutic properties not exhibited by the crude drug, but they do not deteriorate, they are more completely absorbed from the intestinal tract and their dosage may be expressed in terms of actual weight rather than as biologic (cat or frog) units. With them, the practice of digitalizing patients rapidly by either the oral or intravenous route is becoming more popular. Attention is also being paid to materials isolated from the leaf of *Digitalis lanata* as well as from the more familiar *Digitalis purpurea*.

Available preparations of partially purified glucosides are

1 *Digilanid*—Digilanid is a mixture of the isomorphous crystallized glucosides A, B and C from the leaves of *Digitalis lanata* in their naturally occurring proportions. This preparation seems needlessly complex and has not attained great popularity.

2 *Digitoxin* (*Digitaline Nativelle*—Fougere *Pourodigin*—Wyeth)—Digitoxin

is obtained by hydrolysis of both varieties of leaf but the commercial preparation is made from the *purpurea* plant. Its action is, of course, similar to that of *digitalis* but full effect may be obtained by the oral administration of only 1.25 to 1.5 mg, given in fractional doses of 0.5 mg at intervals of from four to six hours. Gold and his co-workers⁶⁷ found that patients could be quickly and fully digitalized by giving a single dose of about 1.25 mg either orally or intravenously, an observation which proved almost complete intestinal absorption in contrast to the crude preparations. The toxic dose, as for other glucosides, was about twice the therapeutic. The usual maintenance dose is 0.1 or 0.2 mg daily.

3 *Lanatoside C* (*Cedilanid*, Sandoz) — This glucoside is found only in the *Digitalis lanata* leaf. One of the first clinical studies was made by Fahr and Ladue,⁶⁸ who felt that the optimum intravenous dose was 8 cc (16 mg). Others^{69, 70, 71} have shown that this dosage will usually reduce the ventricular rate of patients with auricular fibrillation to a normal level in three to four hours with no evidence of toxicity, but we have felt that this lack of toxicity is more apparent than real and are in the habit of reinforcing the intravenous procedure immediately by giving 0.1 gm of the powdered *purpurea* leaf orally two or three times daily until the patient has been unquestionably controlled. Rapid digitalization with cedilanid may also be achieved orally by giving 8 mg in tablet form. The recommended oral maintenance dose is 0.5 mg three times daily but we feel that this is often inadequate, we furthermore see no advantage in using pure glucosides for this purpose and have returned to the powdered leaf for continued treatment. We are enthusiastic, however, about the intravenous use of cedilanid and frequently employ it in ambulatory patients as it simplifies treatment considerably. It comes in 4-cc ampules, each cubic centimeter containing 0.2 mg.

4 *Digoxin* (Burroughs-Wellcome) — This drug is obtained from the hydrolysis of lanatoside C. We have had no experience with it but see no reason why it should not be a satisfactory product. Schwab⁷² rapidly digitalized patients by the intravenous injection of 1.5 mg followed in six hours by 0.5 mg, only slightly slower clinical responses were obtained by the oral administration of 2.0 mg (a single dose) followed six hours later by 0.5 mg. This shows that intestinal absorption is rapid and almost complete. Maintenance was difficult because of rapid excretion and frequently required 1 mg a day or more.

5 *Ouabain* — A glucoside isolated from *Strophanthus gratus* is suitable for parenteral use only. In undigitalized patients the maximum intravenous dose is probably 0.5 mg in twenty-four hours. Eichna and Taube⁷³ assayed several glucosides clinically by giving them intravenously in equal gram-molecular doses to the same patient under fairly standard conditions and rate them according to speed of action in the following order — ouabain, digoxin, lanatoside C and digitaline native. The differences are not great, however. Eichna and Taube⁷⁴ gave single intravenous injections of ouabain or digoxin to patients with congestive heart failure and observed that the initial measurable response was a fall in venous pressure.

Synthetic Glucosides — Chen and his associates⁷⁵ have prepared an interesting series of synthetic glucosides but the work has probably not reached the stage of clinical trial.

Diuretics — Combinations of mercury and theophylline are now available for oral use as salyrgan-theophylline tablets (Winthrop Chemical Co., Inc.) and mercupurin tablets (Campbell Products, Inc.). They are regarded as not entirely free from toxic properties but suitable for patients who do not require drastic and prompt diuresis.^{76, 77} Their action may be enhanced by simultaneous administration of large doses

(8 to 12 gm) of ammonium chloride* daily. Treatment may be begun with one tablet three times daily for four days, but this amount may be doubled or a single dose of five tablets may be given if more rapid diuresis is required. If no diuresis results, the attempt should be abandoned as mercury retention and poisoning may occur. Nausea, vomiting and mild diarrhea frequently occur. The reactions (some of them instantly fatal) which rarely follow the intravenous administration of mercurial diuretics have been reviewed by Wexler and Ellis⁷⁸. The fatal ones are evidently due to cardiac arrest but in comparison with the number of injections given are extremely rare. Digitalis intoxication may occur if edema fluid is mobilized too rapidly.

Rheumatic Fever—Coburn⁷⁹ in a report which covers a period of two years' observation showed that in twenty patients in whom a blood salicylate level of 259 to 400 gamma for each cubic centimeter was maintained by daily intravenous injection of *sodium salicylate*, there was a prompt subsidence of activity in the rheumatic joints and a rapid return of the sedimentation rate to normal, but that in twenty patients with levels below 250 gamma, activity persisted. Valvular heart disease did not develop in any of the thirty-eight patients given at least 10 gm of sodium salicylate daily. On the other hand, twenty-one of sixty-three rheumatic patients given smaller doses exhibited signs of valvular disease.

A recent report by Smull, Wegria and Leland⁸⁰ indicates that the administration of sodium bicarbonate with salicylates in rheumatic fever may prevent the establishment of a satisfactorily high serum salicylate level.

Important studies by the Army⁸¹ and Navy^{81a} have demonstrated a dramatic reduction in the incidence of hemolytic streptococcal infections, rheumatic fever and respiratory infections as a result of the prophylactic use of 0.5 to 1.0 gm of *sulfadiazine* daily. In a large combined series the incidence of toxic reactions was almost negligible, and no evidence of mass sensitization has yet appeared.

Subacute Bacterial Endocarditis.—Neither the sulfonamides nor the anticoagulants alone or in combination have produced any striking reduction in the mortality rate of this disease. Earlier reports on penicillin were likewise disappointing, but it is hoped that the employment of larger doses may prove helpful. A recent report looks promising.*

Angina Pectoris.—Levine⁸² reports that testosterone propionate has no useful action in angina pectoris, contrary to earlier enthusiastic reports.

Hypertension.—The literature is full of reports praising alleged hypotensive drugs, particularly the sulfocyanates, but all of the recent, well controlled studies⁸³⁻⁸⁶ reveal failure to demonstrate any useful property. Even vitamin A has acquired its supporters but, although it does interesting things to renal function, it has failed to reduce blood pressure.⁸⁷ Goldblatt and his associates⁸⁸ have applied the same drugs to

* J.A.M.A., 127:129, 1944.

animals with experimental hypertension and also found them valueless. There is no statistical proof that medical treatment reduces blood pressure or prolongs life.

Paroxysmal Tachycardia—Boyd and Scherf⁸⁹ revived interest in magnesium sulfate by reporting that the intravenous injection of 20 cc. of a 20 per cent solution terminated eight separate attacks.

GASTROINTESTINAL TRACT

Achlorhydria—Koehler and Windsor⁹⁰ have reopened the problem of *acid therapy* in digestive diseases accompanied by achlorhydria. Titration experiments suggest that a normal meal evokes the secretion of about 35 cc of dilute hydrochloric acid (U S P) and that the normal pH of gastric contents after eating a meal containing 40 gm of protein drops to about 1.6. To attain such a figure clinically would require the administration of 510 drops of dilute hydrochloric acid or 20 capsules of glutamic acid (420 mg each) with each meal. This is a manifest impossibility and emphasizes the futility of the usual dosage.

Peptic Ulcer—Fogelson and Shoch⁹¹ have suggested that the effectiveness of antacid therapy depends not on the neutralization of hydrochloric acid per se but on the consequent inactivation of pepsin. They claim to have produced symptomatic remission in twenty-six of thirty-four cases of intractable ulcer pain with *sodium alkyl sulfate*, a substance which inactivates pepsin without affecting the pH of gastric juice. *Sodium lauryl sulfate* (contained in Dreet) has received much publicity but we have seen no well controlled reports.

Insoluble Sulfonamides—Sulfaguanidine has proved to be too toxic. Succinylsulfathiazole and phthalylsulfathiazole (sulfasuxidine and sulfathalidine, Sharpe & Dohme, Inc) have no effect on the typhoid-paratyphoid group of organisms or on protozoa, but they produce significant reduction in the total number of clostridia, anaerobic cocci and particularly of the coliform bacilli.⁹² The antibacterial mechanism is unknown but the drugs are recovered from the stools in high concentration and little is reabsorbed into the blood stream.

Bacillary dysentery is well controlled by any sulfonamide. The acute phase is probably a systemic disorder and responds promptly to the soluble compounds, sulfathiazole and sulfadiazine being the most effective. For the chronic or carrier state, however, the insoluble preparations are to be preferred. Basing his opinion on the work of Hardy and associates,⁹³ Keefer⁹⁴ suggests that patients with acute dysentery be treated for four days with sulfadiazine and thereafter with sulfasuxidine until stool cultures are negative. Poth and Ross⁹⁵ later showed that sulfathalidine is much more effective than sulfasuxidine in the presence of watery diarrhea, the suggested scheme is 0.04 gm for each kilogram of body weight every four hours for twelve doses, after which 0.02 gm is given at four-hour intervals for at least seven days.

Flexner strains of *Shigella paradyserteriae* are more sensitive to sulfo-namide action than the Sonne variety⁹⁶

These authors, who treated six cases of *chronic ulcerative colitis* with 0.02 gm for each kilogram six times daily for four weeks, claimed satisfactory clinical response. Since the etiology of this disease is unknown, however, it can scarcely be regarded as curative. Our experience leads us to support Poth's⁹² statement that "remissions can be initiated and sustained in approximately one-half of unselected cases of ulcerative colitis." Svartz⁹⁷ thought salicylazosulfapyridine the best drug for this disease. Doubtless others will be developed although the toxicity of sulfathalidine appears to be extremely low. If agranulocytosis appears, crude liver extract parenterally should be tried.^{98 154 155}

Many surgeons feel that these compounds benefit the patient who is to undergo intestinal surgical procedures, some⁹⁹ even claiming that multiple stage operations for cancer of the colon are no longer necessary. It seems likely that these drugs might offer some protection against leaking through suture lines.

LIVER AND PANCREAS

Experimental Hepatic Damage—Studies of the effect on the liver of such toxic substances as phosphorus, carbon tetrachloride, arsenic, copper, alcohol, chloroform, selenium, manganese and tar have not been fruitful from the standpoint of human pathology. The experimental production, prevention and treatment of dietary hepatic injury, however, is a new and exciting field. Results are already so dramatic that it is probably no longer legitimate to advise such surgical procedures as splenectomy and omentopexy for patients with portal cirrhosis. For many years textbooks contained at least the implication that this disease is caused by an unidentified toxin but there is now enough evidence to justify the assumption that it is really a deficiency disorder. The prognosis is, of course, much brighter for those who receive an early diagnosis. Since similar experimental deficiencies have also produced profound degenerative changes in the kidneys and other organs,¹⁰⁰ it is to be hoped that more will be learned about such conditions as the "hepatorenal syndrome," bilateral cortical necrosis of the kidneys, nephrosis and other similar conditions.

György¹⁰¹ has reviewed the experiences of himself and other investigators which have made it possible to produce regularly in rats the syndrome of fatty infiltration, necrosis and cirrhosis of the liver with jaundice, hypoproteinemia, ascites and pleural and pericardial effusion. He states that the hepatic lesions are strikingly similar to those of acute yellow atrophy in man and to those produced experimentally by such poisons as carbon tetrachloride. A diminished quantity of casein in the diet seems to be the important inciting factor. The administration of choline and cystine together or of methionine alone is effective in preventing and curing the disease. In transferring these results to man he calls attention to the fact that most alcoholics subsist on a low protein diet with an inadequate intake of the vitamin B complex (including choline). Anorexia, histologic changes in the liver and increased bromsulfalein retention¹⁰² developed in dogs fed a vitamin B complex free diet. Chaikoff and Conner¹⁰³ believe that the presence of excessive amounts of fat in the liver lead slowly to fibrosis and cirrhosis. Ariel and his co-workers¹⁰⁴ review the evidence which supports the belief that a high concentration of lipids in the liver promotes ischemia and

dehydration and that adequate supplies of protein and glycogen protect the organ against various toxins Hough and his associates¹⁰⁶ have shown that in dogs fed a high fat diet deficient in protein or choline, there develop abnormal liver function tests which are improved by the ingestion of choline or methionine. The factors which predispose to liver damage seem to be, then, a low protein, high fat diet containing cystine but lacking in choline and other lipotropic factors listed below

Lipotropic Substances—Developments in this field are so new and so rapidly changing that no definite statements can be made Only the barest outline is presented here with the full realization that today's opinion will surely be modified tomorrow

Shortly after the discovery of insulin it was found that in depancreatized dogs maintained on insulin, there frequently developed fatty infiltration of the liver and that this change was preventable by feeding raw pancreas Lecithin was then found to be effective and when choline was identified by Best, Hershey and Huntsman¹⁰⁶ as the active constituent, the problem became alive Comprehensive reviews have recently appeared^{107 108} Suffice it to say here that a large number of substances have been found which have lipotropic activity, i.e., they are able to prevent the deposition in and to accelerate the removal of fat from the liver under certain experimental conditions Conversely, there are other substances which increase the severity of nutritional hepatic damage The following is a partial list of these materials

Lipotropes

raw pancreas
lecithin
choline and derivatives
betaine
casein
tyrosine
methionine
lipocaiic
cystine plus choline
inositol
ethanolamine

Antilipotropes

cystine
cysteine
homocysteine
low protein, high fat diet
cholesterol
alcohol
liver extract
thiamine
riboflavin
pyridoxine
pantothenic acid
nicotinic acid
biotin

There is much uncertainty about these lists and some of the contradictions may be more apparent than real The cystine effect may be nonspecific The presence of constituents of the vitamin B complex among the antilipotropes may represent nothing more than their capacity to assist in the conversion of carbohydrates into fats Lipocaiic, claimed by Dragstedt and his co-workers¹⁰⁹ to be a new pancreatic hormone, may owe its activity to its content of choline, inositol and

other substances, in any event, there is no convincing evidence that it is really a hormone.¹¹⁰

The common denominator here is not apparent but it appears that choline is the important factor and that other substances may act as precursors of choline by contributing free or labile methyl radicals.¹¹¹ In ways which are not yet clearly understood choline is apparently concerned with the turnover of phospholipids.¹⁰⁸ It should be realized that not all fatty livers are alike, the effectiveness of a given lipotropic agent probably depends upon the chemical nature of the liver lipid in question. Obviously this field is in its clinical infancy.

Clinical Implications—In the management of hepatic disease György¹⁰¹ suggests the employment of a high protein, low fat diet, supplemented by methionine (from 2 to 4 gm daily) or by cystine plus choline (from 2 to 4 gm of each daily). He thinks that these same measures should be employed when the liver has been damaged by burns, shock, anesthesia or poisons. Unfortunately, methionine, cystine and choline in these amounts are extremely expensive.

Miller and Whipple¹¹² have noticed that methionine or cystine plus choline are effective in combating the liver damage due to chloroform anesthesia. Goodell and associates¹¹³ have shown that methionine protects dogs on a low protein diet from the hepatotoxic action of mapharsen. Beattie and his associates¹¹⁴ successfully treated a case of carbon tetrachloride poisoning with infusions of a casein digest (amino acid) to which methionine was added. Ariel and his co-workers¹⁰⁴ suggest that "patients who frequently come to operation with fatty infiltration of their liver (as do those with gastro-intestinal cancer and bile duct obstruction) should be given preoperative glucose and lipocain in order to restore toward normal their altered hepatic chemical constitution." Patek and Post¹¹⁵ made a major contribution to the therapy of Laennec's cirrhosis by showing the pronounced beneficial effects of a high protein, high carbohydrate, low fat diet supplemented by vitamin B complex concentrate. Fagin and Zinn¹¹⁶ reported that the intravenous administration of amino acids in patients with cirrhosis of the liver is frequently followed by obvious clinical improvement. The importance of fatty infiltration of the liver in chronic alcoholism has been emphasized by Conner.¹¹⁷ One may expect to see reports dealing with the dietary treatment of the fatty livers seen also in diabetes mellitus, hypothyroidism, Wilson's disease and epidemic hepatitis. Such studies are urgently needed in the latter disorder particularly.

Pancreatic Insufficiency—Textbooks of pharmacology generally give the impression that oral administration of pancreatic enzyme is ineffective. Recent clinical experiences, however, point to their efficacy in the management of pancreatic steatorrhea.^{118, 119, 120} Triple strength pancreatin in enteric-coated capsules is available but must be given in daily doses of 12 to 25 gm.

BLOOD AND BLOOD SUBSTITUTES

Blood Coagulation—The problem of the relationship of *aspirin* to epistaxis and gastric hemorrhage has been brought forward again by some very interesting findings Paul¹²¹ performed gastroscopic examinations in 182 patients, 107 had no abnormalities, sixty-two had chronic gastritis and thirteen showed evidence of ulceration, polyps or carcinoma After the administration of 15 grains of aspirin, no evidence of hemorrhage, hyperemia or other physical changes in the gastric mucosa was observed Thirty-nine other cases of ulcer or dyspepsia were observed twenty-four hours after the ingestion of 50 to 80 grains of aspirin and no tendency to hemorrhage was noted Seven other patients who had a history of hemorrhage following the use of aspirin were examined following the ingestion of aspirin with negative findings

At about this time, Link and his associates¹²² showed that dicoumarol was broken down in the body into salicylic acid and that salicylates in rats produced prothrombinopenia which could be prevented by the administration of *vitamin K* These discoveries have been applied to humans by several observers^{123 124} They have shown that the administration of salicylates increases the prothrombin time, especially if salicylate therapy is prolonged It has been calculated¹²⁵ that 1 mg of vitamin K will approximately counteract the action of 1 gm of salicylic acid on the prothrombin time

It is to be noted that the average dose of vitamin K in the form of menadione bisulfite is 1 to 5 mg daily Dicoumarol has been found to exert its action by inhibiting the formation of prothrombin and causing a prothrombinopenia The usual therapeutic doses of vitamin K do not prevent this action Large amounts of synthetic vitamin K such as 64 mg in single doses, have produced satisfactory responses in all but two with prothrombinopenia induced by dicoumarol¹²⁶ These large amounts of vitamin K caused no toxic reactions

The problem of the use of *dicoumarol* is far from settled¹²⁷ Dicoumarol has the advantage of being extremely inexpensive, it can be given by mouth and by lowering the prothrombin time might be expected to prevent thrombosis It does not delay coagulation and may cause serious bleeding As previously noted, however, if spontaneous hemorrhage occurs, synthetic vitamin K may be used or the natural vitamin K₁ oxide^{127a} or blood or plasma given In comparison with heparin, the action of dicoumarol is relatively slow in development and disappearance It is clear that patients receiving dicoumarol should have frequent determinations of the prothrombin time Quick¹²⁸ has produced evidence suggesting that prothrombin may have two components One part (A) decreases on cold storage, the other (B) is affected by dicoumarol and vitamin K deficiency Banked plasma which loses component A, is however effective for treatment of prothrombinopenia due to dicoumarol

A comparison of dicoumarol and heparin is given in the accompanying table

	<i>Dicoumarol</i>	<i>Heparin</i>
Mechanism of action	Prevents prothrombin formation*	Blocks action of prothrombin† or thrombin
Rapidity of action	In 24-48 hours	Immediate
Duration of action	Prolonged	Transitory
Method of control	Prothrombin time	Clotting time
Toxic effects	Predisposes to hemorrhage	Predisposes to hemorrhage
Method of administration	Oral	Intravenous or intramuscular in beeswax
Cost	Cheap	Relatively expensive

Heparin seems to be of considerable value in the treatment of venous thrombosis and pulmonary embolism, and as is well known, its effect is to prolong the coagulation time of the blood. Consequently, if heparin is used, the coagulation time must be observed daily. De Takats¹²⁰ has developed a test for heparin tolerance in which the patient's coagulation time after a standard intravenous dose of heparin is determined. This test indicates that some patients are resistant to heparin, and vice versa. He, as well as Rhoads and his associates¹³⁰ and others,¹³⁷ believe the dicoumarol and heparin should be used together.

Thus, a single intravenous dose of 5 cc of heparin can be given immediately in a case of emergency, followed by intramuscular doses. Bryson and Code¹³¹ have administered a suspension of powdered heparin and beeswax subcutaneously and have found that a prolonged coagulation time will develop in the experimental animal. Following the intravenous administration of heparin, dicoumarol may be begun by mouth. In a series of fifteen patients reported by Rhoads, Walker and Panzer¹³⁰ there have been no accidents, but in one year we saw three cases of cerebral hemorrhage occur during heparinization. It is suggested that the prothrombin time be maintained somewhere between thirty-five and sixty seconds while dicoumarol is being used. Caution should be taken in the administration of the drug in those cases with ulcerating or granulating wounds or liver disease, and it is now believed to be contraindicated in subacute bacterial endocarditis.¹³² We suspect that the use of these materials will soon become unfashionable.

Of related interest is the report by de Takats, Trump and Gilbert¹³³ on the effects of *digitalis* on the blood-clotting mechanism. Their studies suggest that *digitalis* favors a tendency toward thrombosis which becomes particularly pronounced in patients with stasis or infection. They have suggested the use of sodium tetrathionate as a drug

Through an inability of the liver to utilize vitamin K

† By union of its mucotin-sulfuric acid like property with an unidentified serum albumin factor. The compound thus formed appears to bind thrombin^{133a} or prevent the invasion of prothrombin to thrombin^{133b}

to oppose the thrombotic tendency of digitalis This drug is administered intravenously

Red Blood Cells—The war has served to accelerate studies on the use of blood and blood substitutes for shock and various other conditions One of these new developments is in regard to the control of hemorrhage associated with severe damage to the liver Kinsey,¹⁸⁴ in five cases of acute yellow atrophy of the liver with hemorrhagic tendency, gave blood transfusions, the blood being fortified by the administration of vitamin K to the donor In four of these cases the method seemed to have a remarkable effect in controlling the bleeding tendencies

For the most part in the present war emergency, blood plasma has been extensively used and is apparently of much greater value in the treatment of shock and burns than whole blood This extensive use of plasma alone has made available large quantities of red blood cells which are usually discarded Murray, Hale and Shaar¹⁸⁵ and Taylor and associates¹⁸⁶ describe a method of preparing a *suspension of discarded red blood cells* in 5 per cent dextrose and/or isotonic solution of sodium chloride In a period of ten weeks Murray gave more than 116 infusions of this red blood cell suspension to patients with anemia The rationale for the use of the red blood cells was that in anemia the only substance needing restoration was the red blood cells themselves They noted two reactions, an incidence of 17 per cent The average rise of hemoglobin for each 300 cc of suspension was approximately 1 gm and all but four of the cases showed clinical improvement Taylor reports on 18,000 such transfusions Another observer has reported the use of a paste of red blood cells in the treatment of chronic ulcerated conditions of the extremities

Fibrin—Two problems awaiting solution in neurosurgery are those connected with hemostasis and those related to the prevention of meningocerebral adhesions An article by Ingraham and Bailey¹⁸⁷ describes the experimental, clinical and pathologic studies on the use of *fibrin foam* as a hemostatic agent and of fibrin film as a substitute for the dura to prevent meningocerebral adhesions Fibrin foam is prepared from human fibrinogen and human thrombin At operation thrombin is dissolved in a saline solution and then the fibrin foam is placed in the thrombin solution and pieces of various sizes and shapes can be selected for use in different conditions The use of the material has shortened neurosurgical operations because of better hemostasis, especially the oozing of blood from the beds of tumors The fibrin foam has also been used with agents such as sulfadiazine and penicillin which apparently do not change the properties of the foam or the tissue reaction

Previous studies of the problem of cerebral adhesions have shown that the ingrowth of dural substitutes into the cerebral wound is the most important factor in postoperative convulsions Ingraham and

Bailey used *fibrin film* composed of 1 part protein and 1 part a plasticizing agent. The protein part is approximately 90 per cent fibrin. The films are smooth, occurring in sheets, and are somewhat elastic. They may be sutured without tearing and can be easily cut to fit any dural defect. Thus far, observations have been made in patients who have had this fibrin film left over the cerebral cortex for a period of eight months and no evidence of cortical irritation has been noted. As with fibrin film, sulfadiazine and penicillin may be used without apparent ill effects on the fibrin film.

Bovine Plasma.—Much effort is being directed toward the problem of preparing animal plasma for use in humans. A recent report by Edwards¹³⁸ is promising in that he has reported no serious toxic reactions in twenty-six patients to whom he gave large amounts of a specially treated bovine serum.

Human Albumin.—Fractionation of plasma by Cohn and his associates¹³⁹ has provided a concentrated blood derivative (albumin) for emergency use. Each gram of albumin is equivalent to 12 gm. of plasma protein or 20 cc. of Red Cross citrated pooled plasma. The standard Army and Navy package contains 25 cc. of albumin in 100 cc. of a diluent. Its osmotic effect is equivalent to 500 cc. of citrated plasma.¹⁴⁰ It is effective in shock due to trauma, hemorrhage, operations or burns. In patients with chronic hypoproteinemia due to liver cirrhosis or nephrosis the beneficial effects were temporary.^{141, 142, 143}

Miscellaneous.—Gelatin solutions have been suggested as a substitute for plasma. As indicated by a report of the National Research Council,¹⁴⁴ there are definite limitations and many unanswered questions concerning its use. Gelatin is not yet considered a satisfactory substitute for albumin or plasma.

Amino Acids.—Elman,¹⁴⁵ who has done so much to advance the cause of parenteral alimentation, has recently reviewed this problem. He points out that whereas a completely satisfactory diet cannot be yet given intravenously, largely because of difficulties concerned with the preparation of fats, it is now possible to give in one liter of solution all of the known protein, carbohydrate, vitamin and mineral constituents. The protein equivalent of 4 units of plasma can be given in the form of 50 gm. of casein digest (Amigen, Mead Johnson & Co.), this contains all of the essential amino acids, will keep the average patient in nitrogen balance, and to it may be added required amounts of sugar, salt and synthetic vitamins. Hartmann, Lawler and Mecker¹⁴⁶ have reported the successful use of these principles in infant nutrition.

ENDOCRINE SYSTEM

Thyrotoxicosis.—Astwood¹⁴⁷ revolutionized the treatment of thyrotoxicosis by the introduction of thiourea and related compounds. A complete review of the physiologic principals involved is not possible here, but they are covered by Rawson and his group¹⁴⁸ who state that

thiouracil induces symptomatic remission in exophthalmic goiter by interfering with the synthesis of thyroid hormone within the thyroid gland. Continued administration produces myxedema and pronounced hyperplasia of the thyroid, the latter because of increased production of the thyrotropic hormone by the anterior pituitary. Williams and Clute¹⁴⁹ have reported their clinical experiences with seventy-two cases of thyrotoxicosis, in all of whom thiouracil caused lowering of the basal metabolic rate, return to normal of the protein-bound iodine of the plasma and satisfactory clinical remission. Himsworth¹⁵⁰ has also had satisfactory results in thirty-two cases but describes a number of untoward reactions. It is too early to state that subtotal thyroidectomy for exophthalmic goiter has been made obsolete by this extremely important drug, but we have not yet found operation necessary since the drug became available to us. In a much smaller experience we have had entirely satisfactory results and only one mild skin eruption as a toxic manifestation. The daily ingestion of 0.6 gm of thiouracil produces a dramatic remission in approximately three weeks, after which a maintenance dose of 0.1 or 0.2 gm daily is given for about six months to prevent recurrence. Its mechanism of action is entirely different from that of iodine, but it is also more satisfactory than Lugol's solution in preparation of the patient for thyroidectomy, should that be thought necessary. Occasionally, exophthalmos may be accentuated, as sometimes occurs after operation, but Salter and Soley¹⁵¹ have described the successful use of large amounts of desiccated thyroid in the treatment of malignant exophthalmos, on the theory that thyroid suppresses the manufacture of thyrotropic hormones.

The most serious reactions from thiouracil have been due to agranulocytosis.¹⁵² Parenteral liver extracts and folic acid have been suggested as specific remedies.¹⁵³ Others^{154, 155} had previously shown that these materials were effective antidotes for leukopenias produced by sulfaguanidine.

Myxedema—Proloid (Maltine Co.) is said to possess the calorogenic activity of desiccated thyroid without the sometimes troublesome cardio-accelerating properties.

Parathyroid Tetany—Until recently parathyroid tetany has been treated by parathormone or A.T. 10. Recent work by several investigators¹⁵⁶⁻¹⁶⁰ has indicated that *massive doses of vitamin D*, up to 200,000 U.S.P. units a day, with added calcium by mouth will prevent parathyroid tetany. They have found no evidence of toxicity, such as hypercalcemia or renal disturbances. This type of therapy is economically cheaper than previous methods. Pope and Aub¹⁶¹ have summarized the recent literature on the parathyroid glands. It is believed that vitamin D influences mainly the absorption of calcium from the gastrointestinal tract, that the parathyroid hormone acts only on phosphorus excretion by the kidneys, and A.T. 10 is effective in promoting the excretion of urinary phosphorus and in large amounts will also

aid calcium absorption. Studies by Albright and associates¹⁰² have suggested that *aluminum hydroxide* be used in the treatment of hypoparathyroidism, as this drug tends to combine with the phosphorus in the intestinal tract, aiding its excretion thereby, as a consequence the serum phosphorus is lowered and the serum calcium is elevated. It has also been suggested by Thorn¹⁰³ that aluminum hydroxide be used in chronic nephritis with tetany on the same rationale.

Addison's Disease—No important therapeutic advances since the introduction of pellet implantation in Addison's disease have been reported. Selye, Hall and Rowley¹⁰⁴ reported the occurrence of vascular lesions in rats, dogs and other animals after prolonged administration of *desoxycorticosterone acetate* and sodium chloride. Perera and associates¹⁰⁵ noted the development of hypertension in eight of twenty-four patients with Addison's disease treated with desoxycorticosterone acetate. As in animals, this rise did not occur on salt alone. They then gave the drug *without salt* to three normal persons and observed a gradual rise of blood pressure which returned to normal within two weeks after the drug was withdrawn. There was neither abnormal retention of the sodium ion nor any increase in the circulating blood volume. The effect apparently was not due to an abnormally labile vascular system as measured by the cold pressor test.

Estrogenic Therapy—Recent investigations have suggested the exciting possibility of using estrogens in the therapy of *prostatic cancer*. Huggins¹⁰⁶ believes that estrogens counteract the stimulating effect of androgens on the tumor cells. In prostatic cancer, especially with metastases, it has been known for some time that the serum acid phosphatase is increased. Several investigators¹⁰⁷⁻¹⁰⁹ have found that the use of estrogens, with or without orchiectomy, has reduced serum phosphatase; this suggests a decrease in the activity of the tumor cells. The results indicate that life is prolonged, the patient is made much more comfortable and metastases may even disappear by means of this treatment. As might be expected, it is by no means a perfect treatment, one distressing complication being pain and swelling of the male breasts.

Enthusiastic reports of a number of new estrogenic substances have appeared. These are mostly synthetic products to be taken orally and the prime reason for their appearance seems to be the claim for greater potency with decreased toxicity, such as nausea and bleeding. Among these new estrogenic substances are (1) ethinyl estradiol (Schering Corp.)¹⁷⁰ 15 micrograms daily in enteric coated tablets for twenty-one days followed by withdrawal for one week, (2) octofollin (Schueffelin & Co.)¹⁷¹⁻¹⁷⁴ in doses of 2 to 10 mg by mouth for from four to seven days (it can also be used in oil for deep intramuscular injections),¹⁷¹ and (3) dienestrol (hvestrol, Wm S Merrill Co.) in doses of from 1 to 4 mg.^{175, 176}

Articles by McCullagh¹⁷⁷ and Smith¹⁷⁸ give excellent reviews of the

use of female sex hormones in such functional disorders as amenorrhea, dysmenorrhea, uterine bleeding, menopause, sterility, premenstrual tension and headaches. Estrogens are also apparently extremely effective in the suppression of lactation. In addition to estrogens in the treatment of premenstrual edema, tension and headaches, McCullagh¹⁷⁷ has re-emphasized limitation of salt intake and suggested the use of ammonium chloride in the second half of the menstrual cycle.

Androgenic Therapy—Using the same rationale for the use of estrogens in the treatment of prostatic cancer, various authors¹⁷⁹⁻¹⁸³ have been investigating the effects of testosterone propionate in the treatment of cancer of the breast. Insufficient time of observation, as well as lack of an adequate number of patients studied, does not permit one to state how effective this therapy might be, aside from the reduction of pain in at least 50 per cent of the cases thus far treated.

It is not the purpose here to discuss the use of testosterone propionate in the treatment of angina pectoris, various endocrine abnormalities or cryptorchidism. It has been found, however, that testosterone propionate will cause retention of nitrogen and revert a patient with a negative nitrogen balance into one with a positive balance.¹⁸⁴⁻¹⁸⁶ Because of this action, Bassett and associates¹⁹¹ have tried testosterone in the treatment of nephrosis, a condition in which there is a constant loss of protein with reduction of the plasma protein level. Their protocol of a 24 year old nephrotic man shows conversion to body protein of 41 per cent of the ingested protein when testosterone propionate was used in comparison to other regimens. About one half of the extra nitrogen utilized contributed to increased proteinuria and the rest was retained in the body. This increase of proteinuria with the slight rise of the concentration of serum protein suggests that there was some increase in the synthesis of plasma protein. They noted, however, that the administration of the drug was associated with the retention of salt and water and the accentuation of edema.

Islets of Langerhans—One of the most fascinating developments regarding diabetes mellitus has been its experimental production in rabbits and rats by the injection of *alloxan*. Observers¹⁹²⁻¹⁹⁶ have shown that this drug causes necrosis of the pancreatic islet tissue and this is followed by persistent glycosuria and hyperglycemia. Further resemblance to the disease in human beings was provided by Bailey, Bailey and Leech,¹⁹⁷ who from four to six weeks after the induction of diabetes in rabbits, found cataracts, slight fatty changes in the liver and some mild tubular degeneration of the kidneys. Because of this specific necrotizing action of alloxan on the beta cells of the pancreas, Brunschwig^{198, 199} injected alloxan into a patient with carcinoma of the pancreas with liver metastases who had recurring attacks of hyperinsulinism of increasing frequency and severity. He believed that this produced significant decrease in the number of attacks. The patient died following laparotomy but the postmortem examination did not reveal necrosis in the malignant islet cells of the liver or elsewhere.

In the treatment of diabetes mellitus a new type of insulin has been placed on the market. It is termed *globin insulin* (Burroughs Wellcome

& Co), containing 80 units of insulin for each cubic centimeter²⁰⁰⁻²⁰³ The onset of the duration of its action is between that of regular insulin and protamine zinc insulin Its hyperglycemic effect may be found two hours after subcutaneous injection and increases rapidly thereafter with a maximum effect coming between the eighth and sixteenth hour after injection The effect gradually wears off thereafter and is practically absent at the end of twenty-four hours The main advantage seems to be the lack of overlapping action with the dose given the next day Furthermore, its maximum activity, if given before breakfast, is associated with the largest meal of the day and during the night the action gradually wears off Bedtime feedings are therefore seldom necessary However, it may precipitate attacks of hyperglycemia, usually late in the afternoon so that supplemental feedings may be necessary

LUNG

One of the most significant possibilities in therapeutics was reported in the article by Crombie and his associates²⁰⁴ on the *treatment of silicosis* by an *aluminum powder* At the present time it is believed that silica changes to silicic acid in the tissues which are destroyed, with resulting fibrosis In 1936 it had been discovered by Denny and Robinson²⁰⁵ that aluminum powder prevented the solution of silicates, the mechanism for which was subsequently found to be due to the coating of the silica particles by a film of crystalline alpha aluminum monohydrate boehmite. In animal experiments it was found that the addition of 1 per cent aluminum powder to inhaled silica dust prevented the occurrence of silicosis, even after prolonged exposure up to twenty-two months

After a careful examination, thirty-four patients with silicosis were treated. Eighteen of these showed little or no disability Eight had complicated conditions, three of whom showed a definitely measurable disability Treatment consisted of the inhalation of aluminum powder through a special apparatus in gradually increasing doses of periods of exposure up to thirty minutes daily for six days a week until two hundred to three hundred treatments had been administered. The following results of the treatment were reported 19 or 55 per cent showed diminution or disappearance of dyspnea, cough, pain in the chest and fatigue. No changes were observed in fifteen cases. Tests of respiratory function showed improvement in twelve of the thirty-six patients Of a group of nine controls who were not treated by aluminum, evidence of progression of the disease was observed in six

MISCELLANEOUS

Lead Poisoning.—Kety and Letonoff²⁰⁶ advocate the administration of *sodium citrate* for the treatment of acute and chronic lead poisoning on the grounds that lead citrate is more soluble and diffusible. The

probable mode of excretion is through the liver, in any event they found that a pronounced decrease in the concentration of blood lead was quickly produced and that satisfactory clinical remission soon followed. In severe cases, 50 cc of a 2.5 per cent solution of sodium citrate was given intravenously. In more chronic cases the drug is administered orally in doses of from 4 to 5 gm in a little water three or four times daily.

Histamine Desensitization—The use of *histamine-azoprotein* (happamine, Parke Davis & Co) in the treatment of allergic disorders has been discussed elsewhere in this symposium (Derbes). We have no rational justification for its use in migraine but have been astonished by the number of patients with periodic headache who claim to have experienced pronounced relief from its use. It is given subcutaneously in ascending doses at intervals of from five to seven days, the average maintenance dose being 0.25 cc. The manufacturers claim that it is a more effective antibody-producer than is plain histamine itself.^{206a}

Chemotherapy of Shock—In an extraordinary paper, Fox²⁰⁷ has reported the successful treatment of severely burned and shocked patients with orally administered *sodium lactate* instead of plasma infusions. By using radioactive sodium he has demonstrated that traumatized skin contains enormous quantities of base and feels that this is at least partially responsible for the great reduction in plasma volume. Basing his clinical studies on the experimental work of Rosenthal,^{208, 209} Fox administered from 7 to 10 liters of one-sixth molar sodium lactate by mouth within the first twenty-four hours and claimed a rapid increase in blood volume without alkalosis. This paper needs careful confirmation, as in many respects it runs counter to accepted ideas regarding shock. It has been skeptically discussed by Harkins²¹⁰ and Cope.²¹¹

Syphilis—*Dichlorophenarsine hydrochloride* has been accepted officially as a safe arsenical for the treatment of syphilis and related conditions. It is more stable, apparently less toxic and possesses a less disagreeable taste than *oxophenarsine hydrochloride* (mapharsen).

Fungus Infections—*Sodium propionate* for the local treatment of fungus infections was introduced by Keeney²¹² with encouraging preliminary results. At a pH of 5.5 in a 1.24 per cent solution of sodium propionate it was found to be fungistatic. Its optimal fungicidal activity, however, existed only in solutions of from 10 to 20 per cent.

RECENT ADVANCES IN THE TREATMENT OF TUBERCULOSIS

JULIUS L. WILSON, M.D., F.A.C.P.*

THE most striking advances in the treatment of pulmonary tuberculosis within the past two or three years have been the introduction of chemotherapy and the continued technical refinements in thoracic surgery. In both instances the new advances are firmly based on scientific developments which preceded them in fields other than tuberculosis—another illustration of the general truth that every new method has its roots in the past. Renewed interest in the chemotherapy of tuberculosis arose with the introduction of the sulfonamides and the remarkable results obtained from the use of these drugs in other bacterial infections. Progress in thoracic surgery has been rapid and steady until it has now reached a point where the experience gained in the treatment of other conditions such as carcinoma of the lung, can now be applied to pulmonary tuberculosis.

Although the steadily declining annual mortality rates from tuberculosis and the new methods of control give reasons to believe that this disease can be practically eradicated in the course of time, this gives scant comfort to the patient with tuberculosis, and the physician must continue to treat the individual. Therefore, these newer developments in treatment offer the hope that by combined attack with chemotherapy and the necessary thoracic surgical procedure arrest of the disease in many more patients will be achieved.

CHEMOTHERAPY

The search for a specific treatment for tuberculosis began long before the discovery of the tubercle bacillus. Vestiges of such once highly regarded remedies remain in our modern methods of treatment in the form of the common belief that milk and eggs, or even such special types as goat's milk or kumyss are specific. The use of cod liver oil has been revived on a scientific basis as an aid to nutrition rather than as an empirical remedy. Following Koch's discovery of the tubercle bacillus, many substances were tried as a specific cure—the heavy metals, iodides and other halogens, creosote and other organic products. With the repeated failure of these medications and the prevailing dogma of therapeutic nihilism there was a long period during

From the Division of Internal Medicine, Ochsner Clinic and the Department of Medicine, Tulane University School of Medicine, New Orleans.

* Associate Professor of Medicine, Tulane University School of Medicine, Associate in Medicine, Ochsner Clinic.

which it was thought that tuberculosis was not amenable to chemotherapy. Even the introduction of arsenical therapy for syphilis by Ehrlich, with the resulting wave of new enthusiasm for chemotherapy, failed to produce any advance in the treatment of tuberculosis. For the past forty years it has been accepted that treatment of tuberculosis must depend on improving the general health of the patient as well as collapse therapy to close cavities and to encourage the natural process of healing. In patients suffering from the exudative, rapidly advancing forms of tuberculosis the physician has remained unable to offer more than supportive treatment.

With the announcement, in 1935, by Gerhard Domagk, of the effective treatment of streptococcal infections with prontosil (the hydrochloride of 2,4-di-amino-azobenzene-4-sulfonamide), the new era of chemotherapy began. It is unnecessary here to review the developments of other sulfonamides more specific for the pneumococcus, the meningococcus, the gonococcus and the staphylococcus. Over five thousand different chemical compounds based on the sulfonamides have been synthesized, only a few of which have been tried experimentally and clinically. The search for one of these which will act on the tubercle bacillus and the leprosy bacillus as a nontoxic, yet effective bacteriostatic agent still continues.

Inherent Difficulties in Successful Chemotherapy—In contrast to the acute infections produced by pyogenic organisms, there are certain inherent difficulties in the successful chemotherapy of tuberculosis by the use of a bacteriostatic or even a bactericidal agent. The first of these is the nature of the bacillus itself. The tubercle bacillus, with its lipid content, stands out among other pathogenic organisms as being notably resistant to chemical and physical agents. Because of its relatively slow rate of growth it would have to be surrounded by a bacteriostatic agent in sufficient concentration for a period of months, whereas hours or days might suffice for control of the streptococcus or the meningococcus.

Moreover, the pathologic lesion produced by the tubercle bacillus is of such a nature that it might be assumed that chemotherapeutic agents would be unable to reach the organisms effectively. The lesions are encapsulated and avascular. By experimental injections it has been shown that they are cut off from the general blood and lymphatic circulation. However, the accuracy of this view is doubtful. The observed facts that toxic substances escape and circulate and that calcium salts are regularly deposited in caseous, encapsulated tubercles indicate that the capsule is permeable to a certain extent. In 1912, Paul A. Lewis¹ showed that vital dyes can not only penetrate tubercles but may actually be concentrated in them. Other experimenters have demonstrated that iodides, iron and other diffusible substances readily penetrate this capsule. On the other hand, colloidal solutions do not. Whether diffusible substances can also penetrate the living cells, the

phagocytes, in which tubercle bacilli often multiply, is not so readily demonstrable

There remains one other noteworthy feature of tuberculosis which militates against successful chemotherapy. This is the chronicity and the relapsing nature of the disease. Symptoms appear months or many years after the initial infection and usually only after the disease is well advanced. Under any kind of treatment, remission, or even apparent cure, is common. Even survival and apparent good health for many years does not guarantee that the disease has healed and been arrested. Only the lasting conversion of a positive tuberculin test to negative or the actual demonstration at necropsy of healed and sterile lesions could prove the effectiveness of chemotherapy.

Experimental Use of Sulfa Derivatives—All of the commonly used sulfonamides and a number of their derivatives still in the experimental stage have been tried against the tubercle bacillus both in vitro and in the experimental animal. Rich and Follis^{2, 3} found that sulfanilamide is inhibitory to the development of experimental tuberculosis in the guinea pig. Feldman and Hinshaw⁴ reported similar results with sulfapyridine. Many other investigators noted this slight but definite effect on the course of experimental tuberculosis if the drug were given at the time of or soon after the infection had been incurred. However in human beings, no definite therapeutic effect could be noted. The well recognized toxic effects of large doses of sulfanilamide, sulfapyridine, sulfathiazole or sulfadiazine administered over a long period of time constituted a danger which outbalanced any noticeable benefit. Therefore, other more potent, more specific and less toxic compounds were sought.

In 1937, Buttle and his associates⁵ demonstrated that diaminodiphenylsulfone was effective against many pathogenic organisms, among which was the tubercle bacillus. However, it was too toxic for clinical use. The first derivative of this preparation to be given thorough experimental trial in this country was *promin* (sodium p-p'-diaminodiphenylsulfone-N, N'-dextrose sulfonate). In 1942, Feldman, Hinshaw, Mann and Moses^{6, 7} demonstrated that guinea pigs infected with tuberculosis and then treated with *promin* not only survived much longer than the controls but also showed definite evidences of healing upon histologic study of the lesions. Guinea pigs tolerated large daily doses of *promin* mixed with their food over a period of several months with no apparent ill effects other than a certain amount of secondary anemia. This work has been confirmed by others.

Diasone (disodium-formaldehyde sulfoxylate, derivative of 4-4'-diaminodiphenylsulfone) was prepared by both Bauer and Rosenthal⁸ and Raiziss⁹ independently in 1938. This substance retained much of its inhibiting effects on the tubercle bacillus and at the same time was much less toxic than diaminodiphenylsulfone. When used on experimental tuberculosis in guinea pigs, an effect comparable to that ob-

tained from promin was noted. As with promin, large and continuous doses of the drug were well tolerated.

Results from the Clinical Use of Promin and Diasone in Tuberculosis in Man—Carrying over the use of these new preparations from the experimental animal in controlled series to human beings in sanatoria has proved to be very difficult. Promin has been tried by Hinshaw, Pfuete and Feldman¹⁰ with promising but not outstanding success. Human beings tolerate a relatively smaller dose of promin than guinea pigs. The disease is more entrenched and the therapeutic effect is difficult to assess. Apparently, the improvement following the use of promin is greater than can be expected from rest alone and the drug exerts an especially beneficial effect on recent and exudative lesions. Certainly, the curative effect is not pronounced. Dancey, Schmidt and Wilkie,¹¹ in a recent progress report on the treatment of human tuberculosis with promin, noted similar therapeutic effects and also observed that secondary anemia developed in all patients treated, practically all were cyanotic, over half had gastrointestinal disturbances, many had headaches, a few had albuminuria, jaundice, psychotic disturbances and rashes, and one patient had paralysis of the lower extremities. Hinshaw, Pfuete and Feldman¹² in another recent progress report found that fresh and exudative lesions are more responsive to promin and that the original trend of improvement has been maintained even after discontinuance of administration of the drug. Faget and his associates of the United States Public Health Service¹³ have reported favorable results from the use of promin in leprosy. They believe that it is the most promising drug that has ever been tried for this disease.

As an unfortunate result of the tendency of our modern magazines to publicize medical and particularly therapeutic information, diasone* (disodium formaldehyde sulfoxylate diaminodiphenylsulfone) was heralded to the public as a specific remedy some months before any scientific report of its use in treating pulmonary tuberculosis in man was available to the medical profession. Obviously played-up by the lay writer as a "sure cure for tuberculosis" and a substitute for rest treatment or collapse therapy, this premature delivery of a new drug, not yet available or accepted, disturbed countless patients and their families, who in turn annoyed their physicians. Petter and Prenzlau¹⁴ then reported the results of treatment of 100 patients with this drug. They found "slight to moderate resolution" in 90 per cent of the cases. The sputum became negative within from forty-five to one hundred twenty-five days in 69 per cent of the cases. Cavities disappeared in 43 per cent of the cases. There was no control series, however, these investigators felt that this group of patients did better than similar patients with other treatment. Patients who would ordinarily have been kept in bed were allowed to be ambulant while taking diasone and any improvement was ascribed to the drug. Toxic manifestations were

* Marketed by Abbott Laboratories

noted in a majority of the patients. All patients became anemic, over 50 per cent turned considerably cyanotic, 25 per cent has gastrointestinal disturbances, 50 per cent had headaches, 25 per cent photophobia and 12 per cent diplopia. They noted no renal damage.

The effect of both promin and diasone on experimental tuberculosis in the guinea pig was excellent and the drug was well tolerated by the animals. On the contrary, the therapeutic benefit in man was much less and the human body tolerated relatively smaller doses rather poorly. Hence, it is obvious that the experimental results in the guinea pig cannot be carried over to man. However, the efficacy of these drugs in producing healing in the guinea pig, an animal most susceptible to the tuberculous infection, suggests the possibility that a sulfonamide derivative or some other drug may be found which will prove equally effective for human beings and less toxic.

SURGICAL TREATMENT

Cavity drainage, lobectomy and pneumonectomy for pulmonary tuberculosis are now being employed in selected cases and are again under study by thoracic surgeons and phthisiologists. Neither direct drainage nor resection of the involved portion of the lungs is new. The fact is that surgical technic, better methods of closed anesthesia and our knowledge of intrathoracic physiology have only recently made possible the reasonably safe execution of the bold therapeutic conceptions of the surgeons of the 1880's and 1890's. Alexander¹⁵ states that drainage of pulmonary cavities has been performed in isolated instances for centuries. As long ago as 1885 deCérenville reported a series of cases in which successful cavity drainage was performed. In 1891 Tuffier¹⁶ resected an indurated tuberculous area in the pulmonary apex and the patient recovered, only to die of an acute infection seven years later. Similar attempts by other men were not so successful and Tuffier's case was long considered an isolated *tour de force*. The field of thoracic surgery had not yet been developed. However, other surgical operations for the collapse of the lung performed exterior to the thoracic cage played a large part in developing this branch of surgery. Before Forlanini introduced artificial pneumothorax, deCérenville in 1885 performed thoracoplasty to collapse the tuberculous lung. Through many modifications and improvements this operation has developed into one of the most frequently used and important methods of treating chronic cavity pulmonary tuberculosis. Phrenic nerve interruption by various operations was introduced and popularized after 1922. Localized collapse of the lesion by plombage and extrapleural pneumothorax were developed for selected cases. During this period the pleural cavity was not invaded by the surgeon except when thoracotomy was performed for empyema. It was not until the development of closed anesthesia made possible wide opening of the thorax that pneumonectomy could be undertaken for carcinoma of the lung.

and lobectomy for bronchiectasis and other suppurative lesions. The successful surgical attack on these conditions, plus the skill required and the improved knowledge of pulmonary physiology, brought about a revival of interest in pulmonary resection for tuberculosis.

Two related observations in the study of cases of pulmonary tuberculosis in which the ordinary methods of collapse therapy fail to close the cavities or to produce sputum negative for tubercle bacilli have stimulated the search for a more satisfactory method of treatment in such instances. The first of these is the "tension cavity." Therapeutic pneumothorax with external pneumonolysis may fail to close these cavities. Similarly, a technically excellent thoracoplasty may fail. The second observation is that up to 10 or 15 per cent of cases of cavitary pulmonary tuberculosis may also have tracheobronchial tuberculosis. In these, collapse of the lung by therapeutic pneumothorax may be positively harmful and thoracoplasty may fail to render the sputum negative for tubercle bacilli. These two observations are related by the fact that involvement of the bronchus draining a cavity may produce incomplete bronchial stenosis which in turn leads to overinflation of the cavity. The treatment of tuberculosis of the bronchial tree itself remains an unsolved problem.

Treatment of the Tension Cavity—The tension cavity may be treated in one of two ways: either drainage of the cavity to the exterior or in certain cases, resection of the lung or portion of the lung in which the cavity lies.

Cavernostomy—Drainage of the cavity to the exterior can be carried out either by the method of Monaldi¹⁷ with prolonged aspiration or by directly opening the cavity to the exterior—"cavernostomy." Monaldi's method of cavity drainage has been widely tried, both in Europe and in this country, since its introduction in 1939. Although it is capable of reducing the size of tension cavities, they tend to reopen promptly when the catheter is removed. Some other form of collapse therapy, usually a thoracoplasty, must then be done at once. Naturally, obliteration of the pleural space is a prerequisite. As the operation is more or less blind, there is serious danger of massive hemorrhage at the time of introduction of the cannula, in most instances the patients react with considerable elevation of temperature due to the introduction of secondary infection, and finally there is apt to be persistent fistulous formation through the thoracic wall. The procedure is essentially unphysiologic. For cavernostomy the pleural space must also be previously obliterated, the cavity must be against the pleura in an accessible location, and other cavities or progressive disease must be absent in that and in the contralateral lung. As a rule the operation is indicated only when other measures of collapse, including thoracoplasty, have been unsuccessful. If thoracoplasty has been performed, and a cavity of the tension type prevents effective collapse, the choice of the surgeon may lie between a revision operation and cavernostomy.

In many such cases revision is most difficult and often unsuccessful. It is these instances that present the best indication for cavernostomy. Eloesser¹⁸ and Shipman, Rogers and Daniels¹⁰ have described a skin flap operation for surgical drainage of such cavities. It is probable that such an operation will be more widely used in the future.

Pulmonary Resection—The second method of treating the tension cavity resisting other forms of therapy is pulmonary resection. Since lobectomy, or even pneumonectomy of a nonadherent lung is a simpler operation than a two or three stage thoracoplasty, there is a temptation to substitute one of these radical methods of resection for other measures of collapse therapy. However, pulmonary tuberculosis in the stages severe enough to require major surgical procedures is seldom confined to one lobe or even to one lung and, of course the lesion here is only a manifestation of a generalized disease. Therefore, lobectomy or pneumonectomy for tuberculosis should be limited to cases with certain definite indications. These are primarily the cases with tuberculous bronchitis producing bronchial stenosis and either large tension cavities or pulmonary suppuration distal to the bronchial obstruction. The operation may also be indicated in cases in which thoracoplasty has been performed with failure to close cavities for control of the disease in the lung, and in some of the rare instances of isolated cavities in the lower lobe where thoracoplasty might sacrifice the healthy upper lobe and other means of collapse might have already failed. In any case, there should not be active disease in the contralateral lung. Dolley and Jones^{20, 21} recorded their experiences with this method of treatment in 1939 and 1940. Churchill and Klopstock²² reported several cases and reviewed the subject in 1943. Alexander²³ has discussed the role of pneumonectomy and thoracoplasty in the treatment of cases with bronchial stenosis. As the procedure is still in its experimental stage, it is too early to comment on the results other than to say that, with the utmost skill of the surgical team, properly selected patients have an excellent chance of recovery. With more experience and with a strict limitation to definite indications it is probable that pulmonary resection for pulmonary tuberculosis will tend to take a definite place in the armamentarium of treatment. Probably not more than 1 or 2 per cent of cases will require this type of operation.

CONCLUSIONS

- 1 The results of chemotherapy of experimental tuberculosis in the guinea pig justify the hope that human tuberculosis, particularly in acute and exudative forms, may be amenable to treatment by similar means.

- 2 The sulfonamide derivatives thus far tried on human beings have been too toxic for general clinical use.

- 3 If drugs can be found which are safe and effective against tuberculosis in the guinea pig there is no reason why other drugs cannot be

discovered to accomplish the same results in tuberculosis of human beings

4 The problem of treating cases of pulmonary tuberculosis resistant to collapse therapy because of bronchostenosis and tension cavities may be solved in some instances either by cavernostomy or by pulmonary resection

5. The combination of chemotherapy and thoracic surgery offers great hope of a more successful treatment of pulmonary tuberculosis in the future

SOME RECENT ADVANCES IN BRONCHIAL ASTHMA

VINCENT J. DERBES, M.D.*

IMMUNOLOGIC CONSIDERATIONS

ALLERGIC bronchial asthma results from the interaction of antigens (foods, pollens, dusts) and antibodies, mediating or effector substances being brought into play. In a recent study Cannon¹ directs attention to the fact that these antibodies have been shown to be modified serum globulins with definitely established chemical compositions. They are produced, in all likelihood, from globulin and are synthesized in stereochemical relationship to the antigen for which they have a specific affinity. This synthesis is modified by the "templating action" of the absorbed antigen. The "antigenic template" is synthesized for the intracellular protein reserves. A wide variety of cells is involved in this process, but especially those of the reticuloendothelial system. Since antibody globulin is specifically modified normal globulin, the mechanism of antibody formation is closely related to that of globulin production. Cannon¹ further shows that the effectiveness of globulin synthesis, and therefore antibody production, is determined by the quality and quantity of globulin reserve continuously available.

It is generally accepted today that these antibodies may be free in the blood stream or attached to tissue cells that is, sessile. Interaction of antigen and antibody in the blood stream is not productive of clinical disease but symptoms may follow coupling of sessile antibodies and antigen. There is a certain amount of evidence to show that histamine may be the mediating or effector substance. Thus, Katz and Cohen² were able to show that there was definite liberation of histamine when red blood cells from persons sensitive to ragweed were 'shocked' in vitro. Furthermore, histamine causes smooth muscle to contract. On the other hand, Rose's³ studies on histamine in patients with allergy do not warrant the conclusion that histamine is released during the attack. Urbach and Gottlieb⁴ have summarized the data supporting the view that perhaps acetylcholine is the substance which mediates anaphylaxis or allergy. All allergic manifestations can be reproduced when this substance is used to stimulate the parasympathetic nerves. The injection of acetylcholine will cause an attack of asthma in an asthmatic patient, this has been suggested as a means of differentiating between cardiac and bronchial asthma. Wenner and Buhr-

From the Section on Allergy, Ochsner Clinic and the Department of Medicine, Tulane University School of Medicine, New Orleans.

mester⁵ showed that the acetylcholine content of the blood is increased in patients with asthma Urbach and Gottlieb⁴ have reported successful results in selected patients with asthma treated with small doses of acetyl- β -methylcholine chloride (mecholyl) At the present time it seems probable that no one chemical is involved but rather that several biologically active substances, including histamine, acetylcholine and probably epinephrine, take part in the precipitation and continuation of the asthmatic paroxysm

The excellent work of Cooke⁶ and his school is leading to clarification of a troublesome question Why should parenteral therapy with ragweed pollen, for example, desensitize a patient, when repeated exposure to the same antigen through the bronchial mucosa results in asthma? Cooke and his associates have presented evidence tending to show that antibodies appearing in the serum of treated persons (allergic or not) are not the same as those appearing from the hypersensitivity itself The one is thermolabile and skin sensitizing and is demonstrated by skin testing The other, which results from specific desensitization, is not capable of sensitizing recipients and is thermostable This latter antibody blocks or neutralizes the antigen before it can interact with the sessile antibody in the bronchiole Loveless⁷ has shown that there is a decrease, at a fairly rapid rate, of the blocking antibody after therapy has been discontinued

PATHOLOGIC CONSIDERATIONS

Lamson, Butt and Stickler⁸ have reported their clinical and post mortem findings in eighty-two adults and four children with "fatal asthma" They could find no evidence of general lymphoid hyperplasia in the four children studied The average age at death in the women was 46.2 years and 55 years in the men The average duration of dyspnea was nineteen years in the women and thirty years in the men It was found that the symptoms of asthma were stimulated by a wide variety of conditions including pronounced interstitial emphysema, extensive atelectasis, pulmonary fibrosis, bronchiectasis, rheumatic heart disease of long standing, hypertension and syphilitic aortitis Since many patients in this series died shortly after the use of morphine sulfate, Lamson and his co-workers advise against the use of this drug or similar depressants in cases of bronchial asthma Vaughan and Graham⁹ have also emphasized the dangers associated with the use of opiates in patients suffering from severe attacks of bronchial asthma They point out that opiates depress the respiratory center and also have a slight bronchospastic effect They believe that the sicker the patient the greater the danger from the use of opiates, in their experience death from acute intractable asthma is rare Lamson, Butt and Stickler⁸ are in accord with the conclusion of Tuft¹⁰ that "there is at present no known pathologic picture, either gross or microscopic, which may be considered characteristic or pathognomonic of asthma"

This last view is somewhat at variance with that expressed by Hilding,¹¹ who believes that the importance of the role of the ciliary mechanism in diseases of the lower respiratory tract, such as asthma and bronchiectasis, has been underestimated. The removal of secretions from the lower respiratory tract is largely dependent on ciliary action. Hilding¹¹ analyzed the records and pathologic material from thirty-nine cases of fatal asthma, twelve cases of influenza and ten cases of bronchopneumonia. The most characteristic findings were the changes in the bronchial epithelium. Metamorphosis has occurred and goblet-like cells had replaced the normal columnar ciliated cells. The ciliary mechanism was apparently lost and a viscid mucinous secretion blocked the air passages and was adherent to the walls. The gradual occlusion of the air passages eventually caused death from asphyxia. Hilding¹¹ believes that the most important pathologic change in asthma is the loss of ciliary function and that this is the principal cause of death in these cases. Experimental work in rabbits in which attempts were made to study the effects of destroying the ciliated epithelium of the bronchi has not proved satisfactory thus far. Bases and Kurtin¹² made a plea for the use of bronchoscopy and suction as a means of removing obstructing secretions. This position is also held by Hilding,¹¹ who suggests that mechanical removal of the secretions by aspiration through a bronchoscope or by tracheotomy should be resorted to as a life saving measure in cases of apparently severe bronchial obstruction by viscid secretions.

THE ASTHMATIC SOLDIER AND THE ARMY

Major R. I. Alford¹³ has recently published an interesting study from a large general hospital on military experience with patients who have bronchial asthma. Although it might seem strange at first that men with bronchial asthma are inducted into the Army, Alford found from a survey of such cases that there was sufficient reason for their induction. Since the history of asthma without confirming physical signs is insufficient grounds for rejection, many were inducted during a period of freedom of symptoms. Others, anxious to join the Army, did not reveal their allergic condition. Furthermore, men with asthma were often accepted because of the pressure exerted on induction boards to fill their quota. Some medical examiners told these inductees that a change of climate would be of benefit or that medical officers would take care of them.

Alford¹³ points out that asthma developed for the first time in some men when they encountered new and powerful, offending agents. Although it is felt that men with bronchial asthma have little or no place in the Army, an effort is still made to salvage men in order to utilize all available manpower. Under the leadership of Colonel S. W. French and Major L. J. Halpin¹⁴ almost every large military hospital has an allergy clinic and extracts are prepared and distributed to other mili-

THE ASTHMATIC SOLDIER AND THE ARMY

Major R. I. Alford¹³ has recently published an interesting study from a large general hospital on military experience with patients who have bronchial asthma. Although it might seem strange at first that men with bronchial asthma are inducted into the Army, Alford found from a survey of such cases that there was sufficient reason for their induction. Since the history of asthma without confirming physical signs is insufficient grounds for rejection, many were inducted during a period of freedom of symptoms. Others, anxious to join the Army, did not reveal their allergic condition. Furthermore, men with asthma were often accepted because of the pressure exerted on induction boards to fill their quota. Some medical examiners told these inductees that a change of climate would be of benefit or that medical officers would take care of them.

Alford¹³ points out that asthma developed for the first time in some men when they encountered new and powerful, offending agents. Although it is felt that men with bronchial asthma have little or no place in the Army, an effort is still made to salvage men in order to utilize all available manpower. Under the leadership of Colonel S. W. French and Major L. J. Halpin¹⁴ almost every large military hospital has an allergy clinic and extracts are prepared and distributed to other mili-

tary hospitals from the Laboratory of the Fourth Service Command. Analysis of the first hundred cases at Percy Jones General Hospital reveals that 71 per cent of patients were discharged and 29 per cent were returned to limited duty.

Alford¹⁸ calls attention to the fact that the disposition board is frequently handicapped in the ultimate fulfillment of its function by the varied conception of nonstrenuous duty by other officers. Thus, one patient on limited duty was doing strenuous exercise as a dock worker unloading ships, another had done well as a cook until he was given commando training, a sergeant, already on limited duty, was put in charge of a cleaning detail, which was the dustiest work on the post. Alford concludes that men with active bronchial asthma should not be inducted into the Army because it is impossible to give a soldier the same environmental protection against dust, molds, pollens, foods or dampness that he can have in civilian life.

UNUSUAL COMPLICATIONS

Rib Fractures—Oechsli¹⁵ has reported fracture of the ribs due to cough in bronchial asthma. The position of the fractures is of considerable interest from the standpoint of mechanism of its production. Oechsli found in his own cases, and those reported, that without exception the fractures are in a line extending from a point about 4 cm from the costochondral articulation of the fourth rib obliquely caudad and lateral to the ninth rib in the midaxilla. In Figure 84 the four fractured ribs can be seen to lie in this same line. Oechsli¹⁵ called attention to the fact that this location corresponds to the heavy muscular attachments of the external abdominal oblique muscle at its interdigitation with the serratus anterior muscle. It is probable that contraction of the abdominal expiratory muscles alone is not the sole cause of fracture. Analysis of previous cases indicated that in all instances the muscles attached to the shoulder girdle and the thoracic wall were tense at the same time that the abdominal muscles were in strong contraction in the expiratory phase of coughing.

Pulmonary Rupture—Derbes, Engelhardt and Sodeman¹⁶ have presented a study of the consequences of pulmonary rupture in the asthmatic patient. After a pulmonary tear the course taken by the freed air determines whether there will be a subcutaneous emphysema, spontaneous pneumothorax, mediastinal emphysema or a combination of any of these. In view of the pronounced thinning of the alveolar walls and increase in intra-alveolar pressure so often present in chronic asthma, these complications should occur frequently, but this does not seem to be the case. In pneumothorax the findings are the same as those seen in uncomplicated instances except that the characteristic signs of bronchial asthma are often superimposed. Among the outstanding symptoms are pain, dyspnea, cough and collapse. There is generally a decrease in tactile fremitus and breath and voice sounds. Hyperresonance

nance together with displacement of the heart and mediastinal structures to the unaffected side may be demonstrated. The outstanding finding of mediastinal emphysema is a peculiar, loud, crackling, bubbling sound which is synchronous with the heart beat. Severe pain, not unlike that of coronary occlusion, may be present. Hamman¹⁷ had described several differential features: absence of constitutional symptoms and evidence of shock, normal temperature and lack of change in the blood pressure and leukocyte count.

We¹⁸ have shown that subcutaneous emphysema may involve not only the neck but may extend to the face, upper extremities, thorax and

Fig. 84—Roentgenogram of chest showing four fractured ribs with callus formation

abdomen. These complications are believed to be secondary to the rupture of a valvular vesicle which is so constructed that air enters more readily than it leaves.¹⁸ We¹⁸ believe that the physician should exercise restraint in the use of mechanical measures because the nature of the lesion is such that with little or no treatment the majority of patients completely recover. Tapping and removal of the escaped air is frowned upon because it disturbs a protective mechanism, namely the equality of pressure on either side of the alveolus. This pressure equality allows for a minimum of movement and maximum healing. Bed rest for about a month and sedatives as needed are thought to be

the most important points in the treatment Thoracentesis should be reserved for those cases of tension pneumothorax in which the intra pleural pressure is such as to embarrass seriously the patient's respiration

TREATMENT

Medical Treatment—A certain amount of the dyspnea of asthma is due to tenacious sputum and the value of expectorants has long been recognized Two interesting studies on sputum have been made by Basch, Holinger and Poncher^{19, 20} They were able to show that sputum could be divided physically and chemically into three types These types are not to be confused with the three layers into which sputum of patients with bronchiectasis separates on standing The first portion of the sputum coughed up, which is the highest in the bronchial tree, is a bronchial mucous plug This is a pathologic product of high viscosity and is the result of changes caused by drying The third part is found in the most dependent portions of the bronchial tree. Basch and his co-workers were able to obtain this portion only by bronchoscopic aspiration This sputum has an extremely high viscosity and a high content of organic and inorganic substances The second portion of the sputum is a diluted liquefied fraction which has a lower viscosity than the third portion from which it arises by means of cough, ciliary action and the pressure of secretions Liquefaction of the sputum may be the result of the secretion of liquid substances into the sputum, the resorption of solid substances or the result of bacterial or enzymatic liquefaction

The second part of the study conducted by Basch, Holinger and Poncher²⁰ was concerned with the influence of therapeutic agents They found that the *expectorant drugs*, ammonium chloride, potassium iodide, fluid extract of ipecac and emetine hydrochloride, consistently liquefied the sputum of patients with bronchiectasis, as evidenced by a decrease in the measured viscosity No differences were noted in the relative efficacy of these drugs with regard to liquefaction Reference may be made at this point to the study of Tuft and Levin²¹ They gave patients iodides intravenously and orally in an attempt to study the expectorant action of this drug Bronchoscopy was performed on each patient and specimens of secretions were obtained at regular intervals following the administration of the drug. The results indicated that iodides are excreted in the bronchi After intravenous injection an interval of between fifteen and twenty-five minutes elapsed before the iodides appeared in the bronchial secretion The appearance of the drug in the sputum was slightly delayed after oral administration From the point of view of expectorant properties these authors found that the intravenous administration of iodides holds little advantage over the oral route

Basch and his co-workers^{19, 20} found that the *inhalation of steam* liquefied the sputum more effectively than did the expectorant drugs

This liquefaction is the result of a reduction in the content of organic and inorganic substances. They found the inhalation of *carbon dioxide* to be an extremely effective expectorant. Such inhalations seem to reduce the amount of sputum within the bronchial tree by stimulating resorption and rendering the remainder more liquid so that it is coughed up more easily. They considered the most effective therapeutic regimen to clear the bronchial tree of pathologic secretions to be a combination of inhalation of steam and carbon dioxide and the administration of expectorant drugs. Unfavorable effects were observed from oxygen inhalation in that it greatly increased both the viscosity of the sputum and its content of solid substances. Codeine sulfate also increased the viscosity of the sputum and ought not to be used with an expectorant if dilution of the sputum is the therapeutic objective. Atropine sulfate was found to act as an anti-expectorant by decreasing the production of sputum and considerably increasing its viscosity.

Maietta²² recommends the use of *ether in oil intramuscularly* in the treatment of bronchial asthma. He reports that the intramuscular injection of 2-cc. doses of a mixture of equal parts of ether and peanut oil produces relief in stubborn cases of bronchial asthma. The immediate effects were transient and unimportant. The taste and smell of ether are immediately perceived and may last a day. Although the injection caused a temporary burning pain, neither induration nor abscess resulted. A few hours later, Maietta's patients were quieter because of the sedative effect and they breathed more easily. The ether excreted in the lungs loosened the mucous plug and favored expectoration. Epinephrine-fast patients were found to respond again. Doses of 2 cc. of ether in oil may be repeated in several hours if indicated.

Shulman³ has written enthusiastically about the use of *sodium 5,5-diphenyl-hydantamate* (dilantin sodium) in bronchial asthma. He was led to use this drug after recognizing the psychogenic aspect of some cases. Seven children with intractable nonseasonal asthma were treated continuously with doses of 0.1 to 0.2 gm daily. Other anti-allergic measures were suspended during the period of investigation. Six of the seven patients were observed for a period of from six to twelve months and were almost free of asthma during this period, even following respiratory infections and emotional upsets. Patients with seasonal allergies were unaffected.

Not all of the newer drugs receive favorable mention. Thus, Logue and Laws²⁴ reported an attempt to develop tolerance to *mecholy*l or to increase the production of cholinesterase by the administration of increasing doses of mecholy. A control series of asthmatic victims receive injections of physiologic saline solution. In the group receiving mecholy. 54 per cent improved, whereas 66 per cent of the controls were better. They concluded that mecholy. is of little value in the hyposensitization of patients with asthma.

*Histamine azoprotein complex** has definite possibilities and will be discussed in some detail. By diazotization Fell, Rodney and Marshall²⁵ combined histamine with despeciated horse serum globulin to form an antigen complex in which histamine acted as a hapten. Guinea pigs and rabbits immunized with histamine azoprotein and sensitized to crystalline ovalbumin were more resistant to a shocking dose of crystalline ovalbumin than nonimmunized controls. It was concluded from these experiments that immunization with histamine azoprotein renders animals resistant to anaphylaxis. Following up this work, Cohen and Friedman²⁶ injected a group of patients with chronic urticaria, atopic dermatitis and vasomotor rhinitis. They began with 0.05 cc of histamine azoprotein and increased this to 1.5 cc at three to seven day intervals over a period of from three months to one year. Precipitin studies in which the collodion particle technic performed on sera taken previous to treatment was employed, yielded negative results whereas those on sera taken after treatment showed the presence of precipitins to the injected complex. Further studies revealed this precipitin to be specific for the histamine portion of the compound. Iontophoretic studies demonstrated that sera containing histamine antibodies were capable of neutralizing histamine to a variable degree. Sheldon, Fell, Johnston and Howes²⁷ reported favorable clinical results in a variety of allergic disorders. I have been favorably impressed by the use of histamine azoprotein in a series of seventeen asthmatic patients observed over a period of approximately four months.

Ruskin²⁸ studied the influence of *vitamin C* on the antihistamine action of various drugs. Sections from the bronchioles of rabbits' lungs were prepared by a special technic permitting microscopic observation. Histamine was used to produce bronchoconstriction and then another drug was added. Drugs antagonistic to histamine permitted the constricted bronchioles to relax. Ascorbic acid did not hasten recovery from histamine contraction but when serving as the acid radical for calcium, ephedrine, benzedrine or epinephrine, it was a histamine antagonist and bronchodilator.

Several papers on *inhalation therapy* have appeared. Westcott and Gillson²⁹ believe that most ambulatory asthmatic patients, and some who are bedridden, can perform simple mechanical breathing exercises which results in some increase in vital capacity. A substantial increase in vital capacity and a proportionally greater subjective relief from symptoms follows the use of inhalation therapy with 1:100 epinephrine combined with regular breathing exercises and postural drainage when these measures are indicated. Dryness and irritation of the throat are among the most frequent untoward effects observed following the use of 1:100 epinephrine solution either by the continuous inhalation method or the bulb vaporizer method. Lockey³⁰ states that these symp-

* Marketed by Parke-Davis under the trade name of hapamine.

toms often disappear if the patient swallows a few drams of warm glycerin immediately after inhalation of epinephrine. He modified the 1:100 epinephrine hydrochloride solution by incorporating 5 per cent glycerin in it. Clinical trials revealed that irritation and dryness of the throat occurred less frequently in 82 per cent of cases among the patients using glycerinized epinephrine solution than among those using the unmodified epinephrine solution.

Barach³¹ maintains that repeated relaxation of spastically contracted circular bronchial muscle over a five to ten day period is apt to result in prolonged freedom from severe asthma. His plan of treatment in hospitalized patients consists of immediate rectal injection of aminophylline in water, followed by the inhalation of a spray of 0.5 cc. of 1:100 epinephrine vaporized by oxygen under high pressure. Some patients receive in addition a spray of 1 per cent neosynephrin hydrochloride. Excitable patients receive hypodermic injections of dilaudid. Following these procedures the patients are placed in a helium-oxygen hood for two hours. Another rectal instillation of aminophylline is given before bedtime, sometimes combined with dilaudid. The entire routine is continued for a period of five days and the rectal injection of aminophylline is continued at home. After discharge from the hospital a saturated solution of potassium iodide in doses of 1 cc. is administered three times daily. The duration of improvement varied from one week to more than a year. Barach³¹ concludes that repeated bronchial relaxation may be achieved by a combination of helium therapy and aminophylline and that this procedure is of great value in terminating status asthmaticus.

SURGICAL TREATMENT

Gay and Rinehoff³² report further observations on the treatment of intractable bronchial asthma by *bilateral resection of the pulmonary plexus*. This operation is to be considered only when all other therapeutic measures have been employed without success. All the cases reported were severe chronic intractable asthma of the intrinsic type with chronic pulmonary infection. The age of the patient and the duration of the asthma were of less significance in the outcome than the amount of pulmonary disease present at the time of operation. Inasmuch as these patients were poor operative risks a high mortality rate resulted (nine deaths in twenty-one cases). Of the remainder eight patients were considerably improved after a short period during which the secondary pulmonary disease subsided.

The question arises as to how good a surgical risk is the asthmatic patient. Gaarde, Prickman and Raskowski³³ reviewed 180 consecutive cases of allergic asthma and asthmatic bronchitis in which major operations had been performed. All of these cases had received careful pre-operative and postoperative allergic care. In twenty-five of the cases (13 per cent) some form of pulmonary complication developed fol-

lowing operation Pneumonia, bronchitis and severe asthma were the most common complications encountered The incidence of pulmonary complications was about equal in patients with allergic asthma and asthmatic bronchitis When postoperative asthma was excluded as a complication, pulmonary complications were about three times as frequent after upper abdominal operations than after lower abdominal procedures Among the general population, the incidence of pulmonary complications following operations on the upper part of the abdomen is approximately twice that of those following operations on the lower part of the abdomen It seemed, therefore, that although asthmatic patients tended to show an increased incidence of postoperative complications following operations on the upper part of the abdomen, the incidence of complications in the group as a whole was not greatly increased

PROGNOSIS

What may be expected from the treatment of bronchial asthma? Unger and Wolf,³⁴ who followed 207 cases of bronchial asthma for seven years, observed that those patients who had been free of symptoms when previously examined were still progressing satisfactorily Two hundred and fifty-two additional cases were studied They were divided into two groups—paroxysmal and chronic asthma The best therapeutic results were obtained among the patients in the paroxysmal group, especially among those whose symptoms were caused by known allergens which could be eliminated A high percentage of these patients began to manifest symptoms in the first decade of life The mortality rate in the entire series was about 10 per cent

THE VENTRICULAR GRADIENT

GEORGE BURCH, M D , F A C P *

THE ventricular gradient had been neglected for several years even though Wilson, MacLeod, Barker and Johnston¹ had indicated the importance of the index. Ashman and his associates^{2, 3, 4, 5, 6} and Bayley^{2, 7} have recently revived the problem by presenting more practical methods for the analysis and interpretation of the ventricular gradient. Because of the importance of this factor in clinical electrocardiography and the recent interest in the subject, it is considered advisable to summarize the literature with the purpose of presenting in a simplified fashion the concept of the ventricular gradient, although its clinical application will not be reviewed in detail. In order to understand the subject more clearly, certain fundamental aspects of the theory of electrocardiography must be reviewed.

In the process of the activation of living cells, such as muscles, electrical phenomena occur which can be recorded by a sensitive galvanometer. The precise nature of the physicochemical changes associated with these electrical processes is unknown. The theories concerning them are similar, although each observer adheres to certain differences in the presentation of his concepts. In the following discussion Ashman and Hull's⁸ method of presentation is employed since it is simple to interpret.

Every living cell has a series of positive charges on the external surface of its wall and negative ones on the internal surface. These are equal in number. Each pair is known as a *doublet*. A living cell surfaced by these doublets is said to be *polarized* (Fig 85, a). If the cell is in a volume conductor, that is, a medium which will conduct electricity in all three directions such as a bath of physiologic sodium chloride solution (the human body is a volume conductor), the electrical phenomena associated with change in the polarized state of the cell can be recorded by a sensitive galvanometer, such as the clinical electrocardiograph. If the electrodes RA (right arm), LA (left arm) and LL (left leg) were placed in the volume conductor (bath of physiologic sodium chloride solution) as indicated in Figure 85 to form the apices of an equilateral triangle around a living "cell" and a stimulus applied at the point indicated by the arrow, the polarized state of the "cell" would be disturbed. The resistance of the cell wall would be lowered locally by the stimulus. The plus and minus charges would

From the Division of Medicine, Ochsner Clinic and the Department of Medicine, Tulane University School of Medicine, New Orleans.

* Associate Professor of Medicine, Tulane University School of Medicine, Consultant in Cardiovascular Diseases, Ochsner Clinic.

then reach each other and be discharged. In so doing the resistance of the adjacent cell wall would be reduced and the adjacent plus and minus charges would also be discharged. This would continue around *ad seriatim* until the entire cell lost its doublets. (The completeness with which the doublets are lost is unknown. It is unlikely that they are lost entirely except possibly with death of the cell. In this discussion, for the purpose of simplicity, it will be assumed that all are lost.) This process of discharging of the plus and minus charges is referred to as *depolarization*, at its completion the cell is said to be *depolarized*.

Fig 85—Diagrammatic representation of a polarized living resting cell, and the stages in the change in the polarized state following stimulation at the point indicated by the arrow. The completed galvanometer recording of the electrical force associated with the changes in the state of polarization are also shown. The size of the solid angle subtended by the cell at the electrode will determine the force offered by the cell at that electrode. The charge of the potential offered by the cell at that electrode is determined by the charge first seen, were an observer to peep through a hole in the apex of the solid angle and look at the cell. In *c* the charge of the field about RA is negative and the one at LA is positive (see text for further details).

From Figure 85, *c*, *d*, *e* and *f* it can be seen that as the depolarization of the cell occurs, the RA electrode finds itself in a field of *relative negativity* and the LA electrode in a field of *relative positivity*. The nature of the charge influencing the electrodes is determined in part by the distances of each electrode to the various charges. An analogy may be made with the field around the anode and the cathode in electrolysis, the field near the former is relatively positive and that around the latter relatively negative. From Figure 85 it can be seen that the intensity of the negative and positive potentials in the two fields about

the RA and LA (the electrodes of Lead I) will vary with the extent of the depolarization of the cell (consult Ashman and Hull⁸ for details)

If the electrodes are connected to a galvanometer and a photographic record made, there results a tracing representing the electrical activity produced by the *depolarization* of the cell. The recorded complex is known as the *wave of depolarization*. If it is assumed that depolarization occurs uniformly around the surface of the cell, a smooth wave will result (Fig. 85). It is also well to remember that the

Fig. 86—The process of repolarization with the repolarization wave (T) written in the completed recording

galvanometer is so connected that when the RA electrode is in a negative field and the LA in a positive field the galvanometer is deflected upward or in a positive direction. Since the fields are such in Figure 85, the depolarization is positive in Lead I. The galvanometer connections are so made that when the LA and LL electrodes are used to record Lead III, an upright or positive deflection is also recorded whenever the LA electrode is in a field of relative negativity and the LL electrode is in a field of relative positivity. During the depolarization of the cell shown in Figure 85, it can be observed that the LA electrode is in a field that is more positive than the LL electrode and

therefore the galvanometer string is deflected to the negative side recording a negative or downward wave of depolarization

Living depolarized cells are endowed with the ability to restore themselves to the resting state by means of certain physicochemical phenomena aided by enzymes reacting with foodstuffs, oxygen and other substances. This restoration begins almost immediately at the site where depolarization first began. If it takes place in a uniform manner, it will occur around the cell in a fashion similar to that described for depolarization. The restitution of the doublets to the original state is spoken of as *repolarization* (Fig. 86). The rate of *depolarization* is more rapid than the rate of *repolarization*, but the intensity of the electrical force attained is greater in the former than in the latter as is indicated by relative amplitudes of the wave of depolarization and repolarization shown in Figures 85 and 86. The repolarization wave is

Fig. 87.—When the order of depolarization or accession is regular and uniform in rate and all portions of the "cell" remain in the excited state for an equal length of time, the order of repolarization or regression must follow the path of accession and will be regular and uniform and the ventricular gradient will not exist.

negative in Lead I for during repolarization the RA electrode is in a field of relative positivity and the LA electrode is in a field of relative negativity thus reversing the polarity and flow of current in the galvanometer and thereby resulting in a deflection below the *isoelectric* or base line or a negative wave (T wave). In Lead III the LA is in a field of relative negativity during repolarization and the LL electrode is in a field of relative positivity. This results in a positive or upright repolarization wave (T wave) in this lead.

The total force represented by the *depolarization* or *repolarization* waves may be measured by determining the area under each curve. The area under each of these waves is equal in Lead I and Lead III (Figs. 86 and 87). One wave is positive and the other negative in each lead (Fig. 87).

The depolarization wave is designated the R wave and the repolar-

ization wave the T wave in order to draw an analogy between this *theoretic* spherical cell of muscle and the human heart and the waves of depolarization and repolarization in the human electrocardiogram

When the living cell is in the depolarized state, it is said to be in the *excited* state. When it is in the polarized state, it is said to be in the *resting* state. If following the application of a stimulus every *portion* of the cell remains depolarized or in the excited state for an equal length of time, it means that the area under the R wave must equal that under the T wave and that the order of *repolarization* retraced exactly the order of *depolarization*. This, of course, indicates also that the areas under R and T must be opposite in sign as well as equal. Therefore, if the values of the areas under R and T are added algebraically, the result is zero, this indicates that the duration of the *excited state* is *equal* throughout the cell. Wilson and his associates made use of this addition in order to express the *duration of the excited state* of the ventricular musculature in absolute units. This expression of the duration of the excited state they called the *ventricular gradient*. In summary, then, the ventricular gradient is an expression of the variations in the duration of the excited state. Later it will be seen that it can be represented as a vector force possessing all of the mathematical characteristics of such a force.

It has been indicated in the preceding discussion that when the duration of the excited state is equal throughout in the hypothetical cell, the ventricular gradient is zero (Fig 87) or there is no gradient. By necessity the order of repolarization has retraced exactly the order of depolarization. Should the duration of the excited state not be uniform throughout, the ventricular gradient will have an absolute value and the direction and magnitude of the vector representing the gradient will be determined by the nature of these variations. For example, in Figure 88, the M half of the cell has been cooled to 15° C, this delays depolarization and the physicochemical processes leading to repolarization so that repolarization begins on the N half first. The duration of the excited state, therefore, is not equal throughout the cell, it is longer in the M half. In the resulting tracing the repolarization wave will also be upright and the gradient will be greater than zero or it possesses an absolute value.

The vector representing the gradient points in a direction from the point in the cell in which the duration of the excited state is longest to that in which it is shortest, in this case from the right of the cell to the left as indicated by the heavy arrow in Figure 88. Obviously, if the N half of the hypothetical cell were cooled, the arrow would point from the left of the cell to the right or if the positions of the electrodes, RA and LA, were exchanged, it would point from the left of the cell to the right. The influence of rotation of the cell will likewise affect the direction. For example, if in Figure 88 the cell had been rotated clockwise through an angle of 180 degrees, the vector representing the

gradient would point from left to right instead of from the right of the cell to the left. Therefore, rotation of the cell or the relationship of electrodes to each other and to the cell will influence the direction, and obviously, the manifest magnitude (defined later) of the gradient.

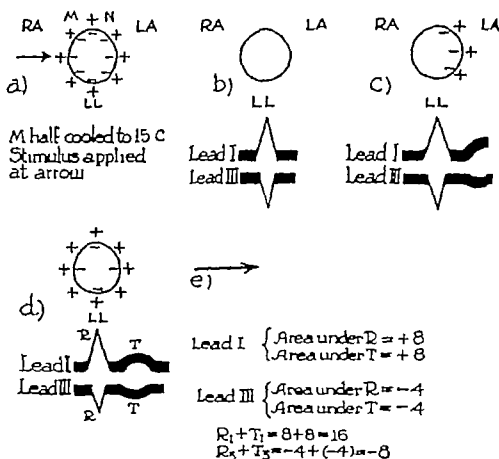

Fig 88—The M half of the cell was cooled to 15 C., thus delaying the physicochemical process in the M half of the cell. When a stimulus is applied to the M half at the point indicated by the arrow, depolarization occurs relatively slowly. When the impulse reaches the N half of the cell, the depolarization process speeds up and progresses in a normal fashion. Since the M half is cooled, the physicochemical process associated with recuperation and repolarization or regression is slowed so that repolarization begins on the N half of the cell (c) thus resulting in an order of regression which is opposite in direction to the order of depolarization or accession. This also results in a pronounced variation in the duration of the excited state for various portions of the cell. In this example the M half remained in the excited state for a much longer period of time than the N half. This also resulted in regression waves (T waves) with areas of the same sign as the areas of the accession waves (R waves). There is a definite gradient. A vector representing the gradient points for the point in which the mean duration of the excited states is longest to the point where the mean duration is shortest. In this example it would point then from the center of the M half of the cell horizontally across to the center of the N half (heavy arrow e).

Again, the vector force expressing the depolarization (R) and repolarization (T) may be correlated independently with the gradient as well as with each other.

Wilson, Bayley, Ashman and their co-workers have applied the same reasoning to the human heart. By determining the area under the de-

polarization complex (QRS) and repolarization complex (T) of the human electrocardiogram and adding these areas algebraically the *ventricular gradient* is determined. It has the same significance as for the hypothetical cell (previously described). It is a vector expression (in quantitative terms), of the relative variations in duration of the excited state in the different portions of the ventricular musculature. It is an expression of the relationship of the orders of depolarization and repolarization. The vector representing the gradient points from the area in the heart in which the average duration of the excited state is longest to that where it is shortest. In the normal human heart the direction is from endocardial surface to epicardial surface and the angle it forms with the horizontal or Lead I line is normally close to that of the QRS complex and close to the longitudinal anatomic axis of the heart.

NOMENCLATURE

From the preceding discussion it is obvious that not only is the ventricular gradient a vector force but so is the electrical axis of the P, QRS and T waves. The anatomic axis (the longitudinal axis of the heart drawn from the base of the heart to the apex) obviously is not a vector force as it possesses only the quality of direction. Bayley² has suggested a type of nomenclature and symbols to represent these forces in order to simplify discussions (Fig 89). The symbols and their connotations are as follows:

G = Ventricular gradient as projected on the frontal plane of the body

A_{QRS} = Mean manifest magnitude of the QRS complex determined algebraically and measured in microvolt seconds or units, i.e. the mean force of the depolarization process of the ventricular musculature

H = Anatomic (longitudinal) axis of the heart as projected on the frontal plane. This value has no magnitude and cannot be expressed quantitatively

A_T = Mean manifest magnitude of the repolarization process in microvolt seconds or units

When the arrow tip or caret (\wedge) is placed over the symbols as follows, \hat{A}_{QRS} , \hat{G} or \hat{A}_T , it indicates that the particular value is to be considered as a *vector*, i.e., it has direction, magnitude and sense. The direction is expressed in degrees according to the old concepts of Einthoven (Bayley suggested the use of the polar coordinate system of measurement, a more correct form mathematically, but because of general practice and until a new method is generally agreed upon it is probably better to adhere to the old empirical method of expressing the direction of the vector forces in order to avoid confusion), i.e., as the angle in degrees the vector forms with the zero or horizontal or Lead I line (Fig 89, α).

It is known that when the three standard leads are used, the electrical forces of the heart projected on the frontal plane of the body (the manifest forces) are the ones recorded. Actually, however, these forces are extended into space away from the frontal plane.^{1 2 3} For example, the H axis projects anteriorly down and to the left, the \bar{G} also points down, to the left and only slightly anteriorly, while the \bar{A}_{QRS} points down to the left and slightly posteriorly (Fig 89, b). In order to represent the spatial vector Bayley² suggested the prefix S be used as fol-

Fig 89—*a*, Triaxial reference system suggested by Bayley² for the analysis of the forces concerned with the electrocardiogram *b*, The spatial vector forces of the QRS (\bar{A}_{QRS}) and gradient (\bar{G}) and the longitudinal anatomic axis of the heart (H) *c*, In the analysis of the standard or limb leads of the electrocardiogram only that portion of the spatial forces projected upon the frontal plane of the body is recorded. These values are called *manifest* values. For example, WX, simply called \bar{A}_{QRS} , is the *manifest* vector force of the spatial vector $\bar{S}\bar{A}_{QRS}$, WY simply called \bar{G} is the *manifest* vector force of the spatial vector $\bar{S}\bar{G}$ and WZ, simply called H, is the *manifest* longitudinal anatomic axis of the spatial axis SH.

lows $\bar{S}\bar{A}_{QRS}$, $\bar{S}\bar{A}_T$ or $\bar{S}\bar{G}$. For example, \bar{G} would represent only that portion of the spatial ventricular gradient that is projected on the frontal plane whereas $\bar{S}\bar{G}$ would represent the entire ventricular gradient as a vector force extended into space, i.e., the spatial gradient. From Figure 89 it can be seen that $\bar{S}\bar{G}$ has a greater magnitude than \bar{G} , the latter being represented by the projected magnitude WY. Furthermore, $\bar{S}\bar{G}$ has three directions. In the normal person it is directed (1) down, (2) to the left and (3) anteriorly, whereas \bar{G} has only two

directions—(1) down and (2) to the left, i.e., it is considered only in one plane, along the frontal plane of the body. The spatial values are of very little use in clinical electrocardiography today but are valuable in the appreciation of the fundamental forces concerned. In fact, it is a necessary concept for detailed understanding of the nature of the forces involved. The spatial force projected on the frontal plane is known as the *manifest* force. It is the force manifested by the completed electrocardiogram.

METHOD OF MEASUREMENT AND RECORDING

Ashman and his associates² have simplified the method of measuring the ventricular gradient to make it practical and still accurate enough to have clinical applications. They suggested the following procedure. The areas of the QRS and T (the depolarization and repolarization complexes) are determined as shown graphically in Figure 90. The

Fig. 90—Diagram showing the areas measured to determine the area under the QRS complex and the area under the T wave. Areas above the isoelectric line are considered to be positive values and those below the isoelectric line are negative.

areas above the isoelectric line are positive values and those below negative. The areas are determined by counting the "squares" formed by the millimeter and time lines or the areas may be determined by measuring the height of a complex in microvolts (1 millimeter is equal to 100 microvolts in a properly standardized electrocardiogram) and multiplying this factor by one-half the width of the base in seconds. A lens for magnification aids in these measurements. The units are expressed in microvolt seconds. Since each time line is 0.04 second apart and each millimeter line represents 100 microvolts with the usual standardization, then each small rectangular division on the tracing represents 4 (often referred to as *one unit*) microvolt seconds (m.v.s.). The algebraic addition of the positive and negative values is equal to the net area of the QRS and T or net magnitude of the depolarization and repolarization processes respectively.

In order to find G , one finds \hat{A}_{QRS} and \hat{A}_T from any two leads, preferably Leads I and III, by obtaining the algebraic sum of the areas of

QRS and T for the two leads and adding them as vector quantities. For example, suppose the net area of the QRS in Lead I is plus 2 and in Lead III plus 6 and the net area of T in Lead I is plus 3 and in Lead III plus 0.5, then \hat{G} would be as indicated in Figure 91

Fig 91—Method of finding the gradient, \hat{G} , from the following values: QRS in Lead I $\approx +2$ units, QRS in Lead III $\approx +6$ units, T in Lead I $\approx +3$ units, T in Lead III $\approx +0.5$ units. \hat{G} has a magnitude of 12.5 units and a direction of $+65^\circ$. A_{QRS} and A_T were first found as described in the text. Then \hat{G} was found by means of the parallelogram law of analysis of vector forces.

More cumbersome methods have been employed to increase the accuracy of the measurements (1) but Ashman and his associates³ have found the method described to be accurate to ± 15 per cent for the magnitude and ± 5 degrees for the direction of \hat{G} .

FACTORS INFLUENCING THE VENTRICULAR GRADIENT

Certain factors will influence the direction and magnitude of the ventricular gradient. These factors are important in health and in disease. Some of the known factors are included below.^{1 2 3 4 5 6 7}

Rotation of the heart about its anteroposterior axis will change the ventricular gradient.² Rotation *counterclockwise* (rotation to the left) will rotate the axis of \hat{G} to the left and make it transverse. The axis of \hat{G} is rotated more than the anatomic axis of the heart. A rotation to the right, or *clockwise* rotation, will make \hat{G} vertical, i.e., \hat{G} will rotate

to the right. The range of normal rotation of \bar{G} is greater than that of the anatomic axis (H), but not as great as that of A_{QRS} .

Rotation of the heart about its longitudinal axis will change the ventricular gradient.² From Figures 89, c and 94 it is obvious that rotation of the heart about the H axis (longitudinal anatomic axis) will change the relationship of the axis of \bar{G} , QRS and H. Bayley, Holoubek and Baker, quoted by Ashman,² have shown that in normal subjects the axis of the gradient should not be more than 24 degrees to the right of the QRS axis and not more than 35 degrees to the left of it.

The influence of *rotation of the heart about its transverse axis* upon the gradient is not well known.²

Posture, by its influence, in a large part at least on cardiac position, will change the gradient.² Standing decreases the magnitude of the gradient and tends to rotate it to the right.

Heart rate will change the magnitude and direction of the gradient² (Fig 92). An increase in rate will tend to decrease the magnitude of the manifest area of the gradient.³ These changes are probably related to many changes associated with the causes for the increase in pulse rate.³

The normal variations of gradient are shown in Figure 93 taken from the work of Bayley.⁷

RELATIONSHIP OF THE VENTRICULAR GRADIENT TO THE QRS AXIS AND THE LONGITUDINAL ANATOMIC AXIS OF THE HEART

Ashman and Byer³ studied the relation of the manifest magnitudes of the axis of the gradient and QRS axis and like Bayley⁷ found the two to be closely related in the normal subject. This relationship is shown in Figure 94. The two axes tend to follow each other rather closely and fall more or less within the range previously quoted from the studies of Bayley.⁷ From a careful study of Figure 94 it can be seen that the spatial arrangement of the QRS and \bar{G} axes about the anatomic axis (H) are such that rotation of the heart along the longitudinal anatomic axis in a counterclockwise direction (when looking at the apex of the heart) will rotate the \bar{G} axis to the left of H and to the right of the QRS axis. Rotation of the heart in a clockwise direction along the longitudinal anatomic axis will rotate the \bar{G} axis to the right of the H axis and the QRS axis to the right of the \bar{G} axis.

NORMAL VALUES OF THE GRADIENT

The manifest magnitude of the \bar{G} averages 13 units (1 unit is equal to 4 microvolt seconds). The magnitude is slightly greater in men than in women. The mean manifest magnitude of A_{QRS} is 5.9 units in women and 6.7 units in men, i.e., \bar{G} is about double A_{QRS} . A 50 per cent increase in heart rate decreases the \bar{G} about 39 per cent in magnitude. The maximum magnitude of \bar{G} is probably not known, but

normally it is near 23 units and the minimum is about 2.5 units. The maximum magnitude of \hat{A}_{QRS} is about 12 units and the minimum about minus 3.5 units.

\hat{G} normally forms an angle of plus 20 degrees or less with the longitudinal anatomic axis (H). \hat{G} rarely is found normally outside of 0 and plus 90 degrees, i.e., it is rarely outside the sixth and adjacent half

Slight clockwise rotation about H

Slight counter clockwise rotation about H

Vertical (frontal plane)

B

C

Fig 94—Correlation of the spatial and manifest axes of the \hat{A}_{QRS} , \hat{G} and H axes as influenced by rotation of the heart. *B*, The spatial axes as seen in a right lateral view when the axes lie in a sagittal plane. The vertical dotted line marks the intersection of frontal and sagittal planes. *C*, The spatial electrical axes after rotation of the heart so that $\hat{S}\hat{G}$ marks the intersection of frontal and sagittal planes.

of the fifth sextants of the triaxial reference system (Fig 89, *a*). As previously mentioned \hat{G} normally lies not over 24 degrees to the right of \hat{A}_{QRS} and 35 degrees to the left of \hat{A}_{QRS} .

Bayley⁷ has stated that if the terminus of \hat{A}_{QRS} describes an arbitrary path about 0, the center, in the triaxial reference system while \hat{G} remains fixed, the terminus of \hat{A}_T describes a similar path (appearing as if rotated through 180 degrees) about the terminus of \hat{G} . The path of

A_T thus describes all possible variations of A_{QRS} . If the terminus of G is made to describe an arbitrary path about 0 while A_{QRS} remains fixed, the terminus of A_T describes a similar path about the terminus of minus A_{QRS} . The path of A_T describes any variations in A_T due to all possible variations in G . These rules make it possible to distinguish primary T wave changes from secondary T wave changes, an important differentiation.

Drugs, fainting and the like⁵ have been studied. A discussion of their effects is beyond the scope of this presentation.

CLINICAL APPLICATION OF THE VENTRICULAR GRADIENT

In disease the ventricular gradient is changed in magnitude and direction as well as in its relationship to the axis of the QRS and the anatomic axis (H). For example, it is possible to interpret the significance of the T wave changes in the electrocardiogram with the use of the gradient. T wave changes secondary to changes in the position of the heart will possess a normal gradient in all respects, whereas if primary T wave changes occur as a result of diseases of the myocardium, the gradient will be abnormal in its magnitude, direction or relation to the other axes. At times all three changes are present simultaneously.^{3, 7} For example, coronary occlusion which produces primary T wave changes will characteristically alter the gradient. In strictly apical myocardial infarction the gradient is shorter or even reversed and located in the third sextant,⁷ whereas a diffuse basal infarction will produce a gradient of excessive magnitude.⁷ In general ischemia of the heart due to impairment of the circulation through the right coronary artery will produce rotation of G to the left or within the first or second sextant whereas ischemia of that portion of the heart supplied by the left coronary artery will rotate G to the right or into the fifth sextant.

When there is doubt about many changes in the electrocardiogram such as low or negative T waves in Lead I in clinically normal persons, the gradient is of paramount assistance in determining the clinical significance of such T waves.

If there is a greater than normal deviation in the angles between the A_{QRS} and G and H axes than would be expected on rotation of the heart alone, it is safe to conclude that there is disease of the myocardium. Such questions frequently arise in subjects with vertical or transverse hearts in whom changes produced by rotation and disease are difficult to differentiate.

It is impossible in a paper such as this to review in detail the explanations for changes in the gradient with each type of disease. With a knowledge of the fundamental concept of the gradient it is possible to arrive at such explanations. A consultation of the works of Wilson, Ashman and Bayley and their associates will assist the reader in these interpretations.

SUMMARY

The literature concerning the ventricular gradient is reviewed. The concept is presented in simple form in order to acquaint the reader with the nature of the problem and the underlying ideas involved. The nomenclature, normal values, some of the normal correlations with the electrical axes of the QRS complex and T wave and the longitudinal anatomic axis are presented. The general clinical applications of the ventricular gradient are indicated, but not reviewed in detail.

RECENT ADVANCES IN THE THERAPY OF CIRRHOSIS OF THE LIVER

LEO J. WADE, M.D.*

CIRRHOSIS of the liver is characterized anatomically by (1) fatty infiltration and necrosis of liver cells, (2) regeneration of liver cells and bile ducts, and (3) a relative increase in fibrous tissue. Clinically, an insidious onset is followed by one or more of the following three acute manifestations (1) gastrointestinal hemorrhage, (2) jaundice and (3) ascites.

PATHOGENESIS AND ETIOLOGY

On the basis of clinical, anatomical and experimental observations one may conclude that fatty infiltration of hepatic cells is sometimes followed by necrosis of these cells with subsequent proliferation of fibrous tissue and attempted regeneration of liver cells and bile ducts.⁶ Any agents or factors which are capable of bringing about fatty infiltration of the hepatic cell if sufficiently prolonged might reasonably be expected to produce cirrhosis. It is probable, therefore, that multiple etiologic agents may produce the disease.

Alcohol is probably not a primary etiologic agent. Cirrhosis cannot be produced experimentally by alcohol ingestion alone and cirrhosis may occur in the absence of excessive alcohol consumption. A common factor among the alcoholic population which is probably of great etiologic importance is *malnutrition*. The dietary habits of the chronic alcoholic are notoriously bad, the diet being inadequate in both quality and quantity of many essential food factors, particularly proteins and the vitamin B complex. Cirrhosis can be produced in the experimental animal by deprivation of certain amino acids and vitamins.^{12, 21, 22} Therapeutic results obtained in human cases by attempting to correct nutritional disorders suggested by these concepts has led many observers to the belief that nutritional factors are responsible for most cases of cirrhosis seen in this country.^{3, 4, 8, 10, 16}

INCIDENCE

Over a ten-year period we have accumulated 175 autopsied cases of cirrhosis of the liver in an autopsy series of approximately 8000 cases.

From the Department of Medicine and the Snodgrass Laboratories of the St. Louis City Hospital, and the Department of Medicine of the Washington University School of Medicine St. Louis, Missouri.

Medical Director of the St. Louis City Hospital. Instructor in Medicine, Washington University School of Medicine. Assistant Physician, Barnes Hospital. Consulting Physician, Missouri Pacific Hospital.

This represents an incidence of 2.2 per cent.* The corrected sex incidence is three males to every two females. The majority of the male patients were in the sixth decade while most of the female patients were in their fifth decade. The patient with advanced disease was on the average five to ten years younger than the patient in whom cirrhosis was an incidental and often an unexpected autopsy finding.

Bartenders, liquor dealers and brewery workers were found among the cirrhotic patients about 50 times as often as among the entire hospital population. Mechanics, electricians, painters, salesmen, time-keepers and watchmen were six to seven times as frequent in the cirrhotic group. Factory workers were about one-fourth as common among patients with cirrhosis.

DIAGNOSIS

As will be emphasized later, success in therapy is dependent upon the early recognition of the disease. Unfortunately cirrhosis is rarely suspected prior to the onset of jaundice, ascites or hemorrhage. The prognosis is grave after the appearance of any one of these three signs or symptoms, 50 per cent of such individuals die within six months¹⁹. It behooves the physician, therefore, to suspect cirrhosis, as he does cancer, before the classical textbook picture appears.

Symptoms—The earliest manifestations of the disease are insidious in onset. *Periodic bouts of digestive disturbances* characterized by anorexia, morning nausea and vomiting, gaseous distention and irregularity of the bowels are common (73 per cent). If these are accompanied by a history of an inadequate diet, chronic alcoholism and an enlarged liver, the diagnosis of cirrhosis should be strongly suspected and therapy instituted unless the above signs and symptoms can be adequately explained on the basis of other demonstrable disease processes.

Weakness and loss of weight follow these earliest manifestations in 95 per cent of the patients. In contrast with the digestive disturbances which may persist for months or even years, weakness and loss of weight are rapidly progressive. Ascites, jaundice and/or gastric hemorrhage soon appear.

Ascites occurs in about 65 per cent of the patients. It is four or five times as common in advanced cases as it is in those with early or minimal lesions. The fluid is a transudate and its formation is dependent upon two factors: (1) a decrease in the serum albumin (below 3.1 ± 0.2 gm per 100 cc¹⁸) and (2) an increase in the venous pressure in the portal system. The decreased serum albumin is the result of

* Reference will be made throughout this paper to the clinical and anatomical findings in 175 autopsied cases of cirrhosis of the liver studied at the St. Louis City Hospital. The author wishes to express his sincere thanks to Lt. Wm I Park, Jr (formerly Assistant Resident in Pathology) for his invaluable aid in the collection of these data.

inadequate protein intake, inadequate absorption and impairment of the liver's ability to synthesize albumin. The increased portal pressure is probably the result of back pressure from the arterial system due to abnormal communications between the branches of the portal vein and the hepatic artery.¹³

Ankle and scrotal edema may precede, accompany or follow the ascites. Decrease in the serum albumin is the precipitating factor in most instances, but pressure on the iliac veins by large accumulations of ascitic fluid may be contributory. Change in the intensity of this latter factor with changes in position may be responsible for nocturnal variations in the ankle edema in some instances.

Hematemesis may be expected in about 70 per cent of the cases. It too is far more common in the advanced case (six or seven times) than

TABLE 1—CHIEF SYMPTOMS NOTED AMONG 175 CASES OF CIRRHOSIS OF THE LIVER PROVED AT AUTOPSY*

Symptoms	Grade 1	Grade 2	Grade 3	Average
	Per Cent	Per Cent	Per Cent	Per Cent
Anorexia	50 0	69 2	79 6	73 0
Loss of weight	66 7	53 2	70 0	64 0
Weakness	83 3	88 2	100 0	93 8
Ascites	17 7	54 8	79 2	62 6
Ankle edema	40 0	58 2	74 2	64 2
Hematemesis	12 5	31 5	67 8	54 7
Jaundice	11 1	30 3	81 2	48 2

* Grades 1 2 and 3 indicate increasing amounts of liver destruction and fibrosis.

in early cirrhosis. Such hemorrhages are probably secondary to rupture of an esophageal varix in most instances although considerable bleeding may result from prothrombin and vitamin deficiencies.

Jaundice is present at some time or other during the course of the disease in 80 per cent of the patients. It is usually not intense and may be of brief duration. Both obstructive and hepatogenous factors are responsible for the bile pigment retention. (See Table 1)

Physical Signs.—A palpable liver may be the only sign elicited on physical examination of the early case. In some instances evidences of multiple vitamin deficiencies are present as well as other indications of malnutrition.

The more advanced case presents a striking picture which can readily be recognized by any sophomore medical student. The sunken cheeks, pinched features, atrophic musculature and muddy complexion (bile pigment retention plus anemia) are in sharp contrast with the large protuberant abdomen usually considered an indication of excess food ingestion. Dilated vascular channels about the nose and occasional

spider hemangiomas on the face, neck and arms may be demonstrated in about half the cases. Pectoral alopecia, scanty axillary hair, a straight pubic hair line and testicular atrophy are common in the male patient. Erythema of the thenar and hypothenar eminences of the hand (liver palm) is present in one third of the cases. The breath sometimes has a "sweetish" odor variously referred to as "new mown hay" or "cow's breath" if liver insufficiency is advanced.

More detailed examination will reveal the diaphragm to be high and to move very little in the presence of ascites. Hydrothorax occurs in 10 to 15 per cent of the cases, such effusions are rarely massive but are easily detectable on physical examination.

TABLE 2 —PHYSICAL FINDINGS NOTED AMONG 175 CASES OF CIRRHOSIS OF THE LIVER PROVED AT AUTOPSY*

Sign	Grade 1	Grade 2	Grade 3	Average
	Per Cent	Per Cent	Per Cent	Per Cent
Ankle edema	40 0	73 0	70 8	67 6

Hydrothorax	7 4	16 7	14 7	14 3
Jaundice	7 4	13 3	52 7	32 5
Palmar erythema†				33 3
Pectoral alopecia (males)†				87 5
Spider hemangiomas†				43 3

* Grades 1, 2 and 3 indicate increasing amounts of liver destruction and fibrosis.

† Observations in thirty consecutive cases of cirrhosis admitted to hospital in past six months.

The skin of the abdomen appears thin and shiny and is traversed by prominent venous channels. A true caput medusae is infrequent. Shifting dullness, a fluid wave and bulging flanks give evidence of the ascites. Removal of this fluid will permit palpation of the liver in most instances (the average weight at autopsy was over 1600 gm). The spleen is usually not palpable unless some antecedent illness or disease is responsible (average weight 333 gm). Edema of the scrotum and ankles is usually associated with massive ascites. Hemorrhoids are described in about one third of the cases. (See Table 2.)

Laboratory Data—Several simple laboratory observations are of invaluable help in making the diagnosis of cirrhosis. Anemia is present in 95 per cent of the cases. It is usually not severe, the average count being about 3.5 million per cubic mm. Two types of anemia are seen: (1) a macrocytic anemia similar to Addisonian anemia due to interference with the production and storage of the erythrocyte-maturing

factor, and (2) a hypochromic microcytic type of anemia due to blood loss. The former type is about twice as common as the latter.¹¹

Decrease in serum albumin occurs in about 95 per cent of these patients. Usually a compensatory increase in the globulin fraction results in a fairly normal total protein and a reversal of the albumin globulin ratio. The serum albumin level is of considerable prognostic value.¹⁸

Numerous *liver function tests* have been recommended. Two are of value in the diagnosis of cirrhosis.²⁰ The cephalin-cholesterol flocculation test is positive in about 98 per cent of the cases. Mateer's modification of the Rosenthal bromsulfalein test is also positive in a high percentage of cases. In the presence of jaundice the latter test is of no value.

Anemia, low serum albumin and a positive cephalin-cholesterol test form a triad which gives great weight to a clinical suspicion of cirrhosis.

Differential Diagnosis.—A word of caution is necessary to remind the clinician that cirrhosis can be confused with a number of diseases. The following are to be considered: alcoholic gastritis, fatty liver of diabetes or pellagra, von Gierke's disease, leukemia, chronic peritonitis due to the tubercle bacillus, metastases to the peritoneum and the liver, chronic constrictive pericarditis, and Pick's disease. The latter two may masquerade under the guise of cirrhosis for many years. Indeed, the duration of the illness has called our attention to three such cases in the past year.

TREATMENT

Intelligent therapy is dependent upon an understanding of the etiology and pathogenesis of disease. If cirrhosis, as has been postulated, is primarily a nutritional disease characterized by fat deposition in the liver which leads to changes in function and structure of that organ, then considerable information is available upon which to base treatment.

Shortly after the discovery of insulin it was noted that insulin did not adequately compensate for the removal of the pancreas of the dog for fatty livers and death ensued unless pancreatic tissue was included in the animal's diet.¹⁻⁹ These observations gave impetus to the accumulation of a mass of experimental data which at present cannot be said to permit any clear-cut conclusions. In short, however, it appears that certain dietary factors (and possibly an internal secretion) exert a *lipotropic effect* and are essential if absorbed fat is to be transported through the liver to peripheral depots. The absence of, or insufficiency of, these factors permits the accumulation of lipids in the liver and results in a secondary fall of the serum lipids.

With these facts in mind it is reasonable to expect that an early or only moderately advanced case of cirrhosis could be arrested by the mobilization of the fat already deposited in the liver and the preven-

tion of any further fat deposition. Accordingly, the following general therapeutic measures are indicated: (1) elimination of any etiologic agent, direct or indirect, such as alcohol and industrial poisons, (2) reduction in the amount of dietary fat available to the liver, (3) assistance in the mobilization of liver fat by the use of lipotropic factors, (4) provision of a diet adequate in all known dietary essentials. The therapeutic regimen used is much the same as that described by Broun and his associates^{3, 4} (See Table 3). Each of these measures will be discussed in turn.

1 If the patient suffers from chronic alcoholism one is faced with a very difficult therapeutic problem. There is probably no great harm in the continued ingestion of moderate amounts of alcohol provided the diet and medications are continued. Usually, however, the two are not compatible. The cooperation of the patient's family, a medical social worker and a psychiatrist are invaluable. It has been necessary on more than one occasion to "rescue" patients from local taverns and admit

TABLE 3—THERAPEUTIC REGIMEN

1	No alcoholic beverages	
2	Choline chloride, 1 to 2 gm. daily	
3	Skimmed milk, 1 quart daily	
4	Vitamin A	10,000 U S P units daily*
	B ₁	2-3 mg daily*
	B ₂	3-4 mg daily*
	Niacin	20-30 mg daily*
	C	50-60 mg daily*
	D	800 U S P units daily*
5	Diet	
	Vegetable fat	50 gm daily
	Protein	90-100 gm daily
	Carbohydrate	Sufficient daily

* Most pharmaceutical concerns dispense vitamin pills or capsules which, in doses of 1 or 2 daily, will adequately fulfill these needs.

them to the hospital in order to prevent interruption of the therapeutic regimen.

2 It is not possible to eliminate all fat from the diet. Such a diet is not practicable and would certainly not be palatable. One can, however, substitute vegetable fat for animal fat thus rendering the diet more palatable and yet markedly reducing the amount of fat carried to the liver. The fat-soluble vitamins must be supplied in another manner. Vitamin A and D concentrates or capsules may be used in quantities sufficient to furnish approximately 10,000 U S P units of A and 800 to 1000 units of D.

3 *Choline* and *methionine* have been used as lipotropic substances. It is thought that methionine is a choline precursor, but the exact mode of action of either substance is unknown.² Adequate information upon which to base dosage is not available. Animal experiments indicate, however, that much larger amounts are required to mobilize liver fat than are needed to prevent such fat deposition.¹⁴ The usual dosage of

choline is 1-gm—daily in three divided doses* It has been possible, however, to give 2 gm daily without any untoward effects in some patients, while others encounter discomfort due to muscarine-like effect (cardiac slowing, increased intestinal movements, and increase of lacrimal salivary and other secretions)⁷ Some experimentation with dosage is necessary with each patient starting, of course, with the smaller dose.

Methionine is costly and not readily available. Adequate quantities are present in milk which also affords a good source of other amino acids as well as minerals. Whole milk should not be used because of its butter-fat content. Patients soon learn to enjoy skimmed milk, however, and may request more than the prescribed quart per day

TABLE 4—SAMPLE DIET

<i>Morning</i>			
Orange juice.	1 cup	Skimmed milk	1½ cups
Cooked oatmeal.	1 cup	Jelly	1 tablespoonful
Whole wheat toast.	2 slices	Oleomargarine*	1 tablespoonful
Coffee or tea	ad lib	Sugar	ad lib
Salt (if no edema)		ad lib	
<i>Noon</i>			
Oysters or fresh cod†	½ cup	Whole wheat bread	2 slices
Potatoes	½ cup	Skimmed milk	1 cup
Vegetables‡	ad lib	Oleomargarine	1½ tablespoonfuls
Salt and sugar	as above	Graham cracker	1
Jelly	1 tablespoonful	Canned pears, apri	
Coffee or tea.	ad lib	cots, or grapefruit	½ cup
<i>Evening</i>			
Cottage cheese	3 tablespoonfuls	Oleomargarine	2 tablespoonfuls
Vegetables‡.	ad lib	Skimmed milk	1 cup
Whole wheat bread.	2 slices	Jelly	2 tablespoonfuls
Pineapple	3 slices	Salt and sugar	as above
Coffee or tea		ad lib	
<i>Bedtime</i>			
Skimmed milk	1 cup	Cookies§	1 or 2

* Select a brand containing only vegetable oils. Olive oil may be substituted in equal quantities.

† Lean meat, or liver, may be substituted.

‡ Avoid cabbage, corn, cucumbers, lettuce, onions and turnips, which are 'gas formers.'

§ To be made with oleomargarine.

4 Close supervision of the patient's food is essential from the onset. Anorexia will interfere with the ingestion of the prescribed diet unless the patient can be impressed with the great importance of eating. As choline mobilizes the liver fat, the appetite improves and one need

* A convenient prescription is as follows

Choline chloride	70	0
Syr wild cherry q.s. ad	240	0
Sig Teaspoonful three times daily		

only guide the patient in his choice of food stuffs. The diet (Table 4) should contain

Vegetable fat	50 gm
Protein	90-100 gm
Carbohydrate sufficient for caloric need	

In order to evaluate choline therapy properly, no attempt has been made in this clinic to increase the vitamin B or C content above the accepted adequate daily intake, for Patek has claimed that the vitamin B complex alone will bring about remissions or cures among cirrhotic patients^{15, 16, 17}. It is recommended, however, that the vitamin B intake be augmented by the use of yeast or concentrates until such time as the patient's appetite has become sufficiently good to assure adequate dietary sources (See Table 4).

RESULTS OF THERAPY

Enthusiasm for any sort of therapy of cirrhosis must be tempered by a realization that spontaneous remissions sometimes occur. One must not be easily discouraged, however, by failure to produce improvement in the moribund patient. Actual proof of the efficacy of the form of therapy recommended must await a statistical comparison of the results before and after the use of this therapeutic regimen. In spite of many failures, however, it is agreed by all who have observed the patients treated that the results are far better and more consistently good than could be explained on the basis of the occasional spontaneous remission to be expected. Two cases will be described which are representative of satisfactory results.

CASE I—History—L. C., a 59 year old white construction laborer, was admitted to the St. Louis City Hospital on August 4, 1942 complaining of indigestion and postprandial bloating sensation of 3 weeks' duration. The patient denied nausea, vomiting, hematemesis or jaundice. Some ankle edema had been noted. The past history revealed the ingestion of two bottles of beer daily but no whiskey.

Physical Examination—The patient appeared to be his stated age. The abdomen was distended. Some evidence of weight loss was present but not marked. Chest and axillary hair were sparse. Few spider hemangiomas were seen about the chest and neck. Few basal rales were present bilaterally. The blood pressure was 114/78. Fluid wave, bulging flanks and shifting dullness were present. The liver was not palpable. Pitting ankle edema, grade 3 plus, was present. There was no apparent increase in venous pressure.

Laboratory Findings

RBC	3.6×10^6	C-C Floc Test	4+
Hb	12.0 gm	Total Protein	7.3 gm %
Urine	Negative	Alb / Glob	0.9
Kahn	Negative	I V Hippuric Acid*	0.41 gm in 1 hr
Icteric Index	15	Bromsulfalein	15% retention

*Measured as sodium benzoate. Values less than 0.80 are considered abnormal.

Course and Treatment—The patient was placed on the low fat diet, given 1 gm of choline, 1 tablespoonful of cod liver oil and 1 quart of skimmed milk daily. Salyrgan was given intravenously in 1 cc. doses at weekly intervals on three occasions.

Diuresis occurred over a period of approximately two months with marked clinical improvement and almost complete disappearance of the ascites and ankle edema. The patient was discharged October 22 1942 with instructions to return to the outpatient dispensary. Check of the laboratory data at this time revealed essentially the same findings as on admission except for an increase in the hippuric acid excretion to 0.96 gm.

Follow Up—During the following three months there were recurrences of some ascites but this cleared prior to February 1 1943 and has not recurred up to the present time. Laboratory data secured on May 19 1943 were as follows:

C.-C. Flocc. Test	Negative
Total Protein	7.7 gm %
Alb / Glob	1.9
Bromsulfalein	none
Icteric Index	4
L. V Hippuric Acid	0.79 gm in 1 hour

The patient is now working six and seven days a week as a farm helper. He no longer takes the choline but does observe the dietary restrictions.

CASE II—History—E. B., a 72 year old white man, was admitted to the St. Louis City Hospital on July 27 1942 complaining of dyspnea, ankle edema and swelling of the abdomen of approximately eight months duration. The patient had consulted a physician in April 1942 who made a diagnosis of heart failure and prescribed digitalis. No improvement in the symptoms was noted. The patient consulted a second physician who referred the patient to a hospital for diagnosis. Abdominal paracenteses were done eight or ten times at approximately weekly intervals. The patient was discharged without any apparent improvement. He then applied for admission in this hospital.

The past history revealed chronic alcoholism of many years duration (6 to 7 bottles of beer and variable amounts of whiskey daily). Tarry stools had been noted several times.

Physical Examination—The patient was an obese white male of approximately stated age. There were bulging flanks, a fluid wave and shifting dullness. The liver was palpable 2 to 3 cm below the costal margin in the right midclavicular line. Hemorrhoids and a 3 plus pitting ankle edema were present.

Laboratory Findings

RBC	4.9×10^6	C.-C. Flocc. Test	3+
Hb	13.8 gm. %	Total Protein	5.9 gm. %
Urine	Negative	Alb./ Glob	1.2
Kahn	Negative	L. V Hippuric Acid	0.45 gm.
Icteric Index	12	Bromsulfalein	20% retention

Course and Treatment—The patient was started on the diet and medication immediately. Abdominal paracenteses were done on August 3 15 and 27 approximately 5000 cc. being removed each time. No subsequent paracenteses have been necessary. The patient's clinical improvement was satisfactory and he was discharged October 16, 1942. The serum proteins had risen to 7.3 with an albumin-globulin ratio of 1.8 but other laboratory observations were unchanged.

Follow Up—The patient has been seen at frequent intervals up to the present time. He remains free of signs or symptoms.

SUMMARY

Clinical observations as well as experimental data suggest, but do not prove, that human cirrhosis is primarily a nutritional disease characterized by numerous dietary deficiencies. Early fat deposition in the liver is accompanied by anorexia which results in increasingly severe malnutrition. Inadequate intake of protein and the vitamin B complex leads to further hepatic damage as well as renders the liver increasingly susceptible to toxic damage.

If liver fat can be mobilized and further deposition prevented, there is sufficient improvement in the patient's appetite to permit correction of the dietary defects. Choline, methionine and a low fat diet have brought about such changes in experimental animals. Clinical experiences suggest strongly that these observations are applicable to human cirrhosis.

A plea is made for the early diagnosis of cirrhosis. Moribund patients with profound liver destruction are obviously beyond the help of any conceivable therapeutic regimen.

DIAGNOSIS OF GASTRODUODENAL DISEASE

JOHN L. HORNER, M.D. *

It was not so long ago that the physician, in diagnosing diseases involving the stomach and first portion of the duodenum, had to depend entirely on the history, physical examination and analysis of the stomach contents and stool. With the discovery that the intestinal tract containing barium could be indirectly visualized by roentgenologic examination, a tremendous forward step was taken. This method was further increased in efficiency by the addition of the filming fluoroscope, or "spot film." Within the past ten years the flexible gastroscope has come into common usage and, although there is still not complete agreement about the significance of all the changes seen in the gastric mucosa, this examination has added a great deal to the elucidation of difficult diagnostic problems. With the addition of the x-ray and gastroscopic examinations it is certainly a very small percentage of lesions in the gastroduodenal segment that escape detection.

It would be impossible in an article of this brevity to discuss all the lesions that may occur in the stomach and first portion of the duodenum, as well as those in the gallbladder, pancreas and other organs which may mimic them. I shall limit myself to the consideration of gastric carcinoma, uncomplicated peptic ulcer and gastritis, which are by far the most common, and together probably account for 98 per cent of the patients with organic disease in this segment of the gastrointestinal tract.

HISTORY

There is a tendency, where dependable radiologic, laboratory and other aids are available, to minimize, consciously or unconsciously, the importance of taking an accurate and complete history. It is true that confirmation should be obtained, if possible, of all diagnoses made from the history and physical examination, but one should not depend entirely on the roentgenologic and gastroscopic findings. Aside from the fact that these aids are not everywhere so readily available that we can use them on every patient with a dyspepsia, they may occasionally lead us astray. For example, the radiologist may find a deformed duodenal bulb and report "duodenal ulcer," whereas in reality this "ulcer" has been healed many years and the patient's complaints are due to an entirely different disease. By a careful consideration of the history it is often possible to make the diagnosis with considerable assurance and

From the Department of Internal Medicine, Washington University and the Washington University Clinics, St. Louis, Missouri.

Instructor in Medicine, Washington University School of Medicine; and Chief of the Gastro-Intestinal Clinic, Washington University Clinics.

obtain additional help only when further events throw the diagnosis into doubt

Ulcer—The description of the typical symptoms caused by duodenal and gastric ulcer has not been improved upon since the last century. The sequence of pain-food-ease means peptic ulceration in a high percentage of cases, particularly when the pain, which is usually called "gnawing" or "burning," wakes the patient at one or two o'clock in the morning. Usually the discomfort occurs one to four hours after meals, is least before the morning and noon meals and worst before the evening meal and during the night, perhaps because the food intake, which stimulates the secretion of acid, is progressively greater during the day. It should be emphasized that in some patients the discomfort is minor, due in part at least to differences in pain threshold, and the sequence of events may be overlooked except under careful questioning. Relief by food, milk and alkalies is almost always admitted except when complications are present.

Two other factors appear in almost every ulcer history—chronicity and periodicity. The complaints have usually started years before and have appeared at infrequent intervals since. The free intervals, however, grow shorter as the story comes up to the present, and the periods of pain become longer. Flare-ups of pain may occur at any time during the year. The popular impression that recrudescences of ulcer activity usually appear in spring and fall is mistaken.¹

It is impossible to differentiate between duodenal and gastric ulcer on the basis of time relationship to meals. The old teaching that gastric ulcer pain occurs an hour or so after meals and duodenal ulcer pain just before the next meal is not borne out by experience. The location of the pain, however, is helpful. In the majority of cases an ulcer on the gastric side causes symptoms in the left upper quadrant or left epigastrium, whereas on the duodenal side the pain is somewhat to the right of the midline. When the ulcer is at the margin of a gastroenterostomy stoma the distress is lower and to the left.

Cancer—It has been well said that cancer has no history. Certainly there is no typical history in early carcinoma. The syndrome of nausea and vomiting, weight loss and upper abdominal discomfort are symptoms of late cancer. Unless a malignant lesion is suspected when the symptoms are slight and vague it will too often be discovered when a palliative operation is the most that can be offered.

Probably the most frequent early complaint is anorexia. There may be vague epigastric distress, a feeling of fullness, belching and coated tongue. In some patients there will be epigastric pain, similar to that produced by ulcer, but usually less periodic and with inconstant relief by food. Difficulty in deglutition may indicate involvement by the lesion of the cardia. If there is weight loss, even though slight, associated with any of these symptoms, x-ray examination should be done.

Gastritis—Inflammatory changes in the gastric mucosa can, and do,

cause symptoms. How frequently they do is still a subject for disagreement. Gastroscoipists often find gastritis where the symptoms cannot reasonably be ascribed to this condition. On the other hand, we have seen many cases in which the course of the patient's distress closely followed the improvement in the mucosal changes. A discussion of this problem was reported in a recent symposium,² and several articles have appeared in the literature of the past few years, but many more controlled studies will be necessary before a sound basis for gastritic symptoms can be established.

The gastritis which appears to be most often associated with symptoms is the hypertrophic form, and the syndrome most frequently encountered is that mimicking ulcer.³ Other findings may be vomiting, hemorrhage, bloating, sour eructations and heartburn. The ulcer symptoms are found often enough to warrant a suspicion of hypertrophic gastritis whenever the x-ray examination fails to demonstrate an ulcer.

Atrophic gastritis, or more properly gastric mucosal atrophy, may be associated with a syndrome of mild epigastric discomfort, anorexia, weakness, nervousness, sore tongue, numbness and tingling of the extremities.⁴ The digestive symptoms may frequently be secondary, in the patient's mind, to the general ones. That this syndrome occurs in many cases of atrophic gastritis I have no doubt. It remains to be explained why the others are not so affected.

Superficial gastritis may at times cause dull epigastric distress, belching and sour eructations coming very soon after eating.⁵

Summary—A careful and complete history will in many cases enable the physician to make a presumptive diagnosis, and in others will give a suggestive lead. In diseases involving the gastroduodenal segment the complaints are usually referred to the epigastrium, or at least the upper abdomen. When the sequence of pain-food ease is encountered an ulcer must be suspected first, then hypertrophic gastritis, then possibly cancer. When the symptoms are vague the diagnosis of cancer or gastritis must be considered as well as 'functional' dyspepsia, cholecystitis, and so forth.

PHYSICAL EXAMINATION

In the diagnosis of gastroduodenal disease the physical examination offers little or no information. In *peptic ulcer* a point of tenderness may be found. Tenderness in the right epigastrium suggests a duodenal ulcer, in the left upper quadrant or left epigastrium a gastric lesion, in the left paraumbilical area a marginal one. The finding of a mass, of course, makes the presumptive diagnosis of *neoplasm*. An enlarged, nodular liver, palpable supraclavicular node, or palpable rectal lymph nodes (rectal shelf of Blumer) indicates metastases already present and hence is confirmatory of gastric malignancy where the history is suggestive. In severe *gastritis* a diffuse tenderness in the upper abdomen, particularly on the left, is often present. With the atrophic

gastritis of pernicious anemia there may be an associated pallor of the skin, glossitis and evidence of spinal cord damage, such as impaired vibratory sense of the extremities, abnormal toe reflexes and disturbances of the position sense and gait

LABORATORY FINDINGS

Gastric Analysis—The analysis of the gastric contents was an important examination in the days before accurate x-ray and gastroscopic observations. Today it is of secondary importance, though it should not be omitted. An adequate test consists of the aspiration of the chyle after at least an eight-hour fast, the subcutaneous injection of histamine (0.25–0.5 mg. average) and the removal of 10-cc. samples thirty and sixty minutes later. All samples are titrated with 0.1 normal sodium hydroxide, with Topfer's reagent the indicator for free acid and 1 per cent phenolphthalein for total acid.

There does not appear to be any particular advantage in using the various test meals with fractional analysis that have been advocated, since the normal range of values found varies within wide limits. Where the x-ray examination is not readily available, however, the test meal may be used to detect gastric motor delay. Winkelstein⁶ has recommended the use of an oatmeal gruel meal simultaneously with the injection of histamine and neutral red. The neutral red is excreted into the stomach only if acid is produced. With this technic he found that true achlorhydria (pH of 3.5 or more) occurred in only 2.2 per cent of a large group of patients of all ages, a much smaller percentage than that found using histamine alone. Nevertheless, Winkelstein's technic is useful primarily where it is important to determine absolute achlorhydria, and not as a routine in gastroenterology. The injection of histamine alone will determine whether the gastric mucosa is readily capable of producing free hydrochloric acid, and roughly, whether too much or too little.

The fasting gastric juice should also be examined for evidence of blood and exudate, the first suggesting definite organic disease in the stomach, though not helping in the differentiation, and the latter suggesting a gastritis. Blood due to trauma from the tube must, of course, be ruled out. Testing for the presence of excessive lactic acid and Boas-Oppler bacilli is helpful in determining the presence of pyloric obstruction due to cancer, since they are found only with the combination of obstruction plus low acidity.

In interpreting the results of the gastric analysis it is important to remember that in ulcer or carcinoma there are many exceptions to the "typical" findings. Some patients with a gastric cancer have normal or even high values, and there are ulcer patients who cannot be considered to have a hyperacidity. Consequently in any individual case the results of the acid analysis are only suggestive and must be fitted into the picture as a whole before they can have any significance. The

sole exception to this is the finding of histamine refractory achlorhydria in a patient previously considered to have a benign ulcer. Benign ulcers occur so rarely, if at all, in an anacid stomach, that this finding should outweigh others and lead to a recommendation for prompt surgery.

In *gastritis* the amount of acid found is, as in other conditions, variable. It may be high in hypertrophic gastritis. It may be low, or absent, in atrophic gastritis. That atrophy is not infrequently associated with normal acid values may be attributed to the patchy involvement of the mucosa, with sparing of some acid-bearing areas. Where the entire mucosa is affected, as in pernicious anemia, achlorhydria is the rule.

The chief value of the gastric analysis, then, is the detection of histamine-fast achlorhydria, particularly in younger individuals. This should *always* cause further investigation.

Stool—The presence of gross blood in the stool rarely suggests gastroduodenal disease. Occult blood, however, as demonstrated by the guaiac or benzidine tests, may confirm the presence of a lesion in this area. The test is not conclusive unless the patient has been on a meat-free diet for forty-eight to seventy-two hours.⁷ A constantly found positive test occurs in carcinoma much more frequently than in ulcer, whereas uncomplicated peptic ulcer is associated with only intermittent bleeding.

ROENTGENOLOGY

In the diagnosis of peptic ulcer and gastric carcinoma the roentgenologic examination is usually decisive. In gastritis, though it may occasionally be suggestive, it is never conclusive.

Peptic Ulcer—The criteria for the diagnosis of gastric or duodenal ulcer are well established. Benign ulcer is most commonly seen in the stomach as a penetrating niche arising from the posterior wall near the lesser curvature above the angulus, and will rarely be missed. The chief difficulty consists in differentiating a benign from a malignant ulcer—a problem which will be discussed below. Where the ulcer is in the antrum or on the midposterior wall, not projecting beyond the outlines of the lesser curvature, it may be demonstrated with the patient in an oblique position or with compression of the stomach wall leaving only a small residue of barium in the niche itself. It is appreciated that a shallow ulcer could be impossible to demonstrate. Also if the niche is filled with thick mucus or debris it may not be seen.⁸

The radiologic diagnosis of duodenal ulcer frequently rests on persistent deformity of the bulb associated with irritability or localized tenderness. Unfortunately only indirect evidence of activity in the ulcer can be obtained in this way. Since the distortion of the lumen is due to spasm, edema or scarring, or a combination of these, a duodenal cap containing a completely healed ulcer often appears very similar to one in which there is a penetrating niche. Furthermore, a de

formity of the cap can result from disease outside the duodenum, e.g., from adhesions secondary to cholecystic inflammation, conversely there may be no distortion even when a crater is present. For these reasons it is important to utilize the filming fluoroscope, or "spot film," in all cases suspected of ulcer. With this device varying degrees of pressure may be applied over the cap at the same time the films are exposed. The

Fig 95—A, Roentgenogram of the stomach of a 44 year old white woman with typical ulcer symptoms of nine days' duration. The only feature suggestive of ulcer is an irregularity of the superior medial border of the duodenal cap. B, Spot film of same patient during compression of the cap revealing a penetrating ulcer niche.

worth of this procedure is well demonstrated in Figure 95. At the time when this patient's ulcer symptoms were most severe routine films showed little or no irregularity of the duodenal cap, whereas the spot film revealed a niche one centimeter in diameter. In subsequent examinations the niche was found reduced in size and in a few weeks was gone. This case, which can be duplicated in any gastroen-

terologist's experience, shows the importance of the spot film in detecting active duodenal ulcers and in following their course

How often can the ulcer niche be demonstrated? Certainly in gastric ulcer the diagnosis is rarely made without seeing the crater. In the duodenal lesion the percentage of the craters seen varies widely with the experience of the examiner, and the care taken. The German physicians, notably Berg, who devised this procedure, claimed their ability to demonstrate niches in the majority of cases.⁹ In the United States increase in familiarity with the method has resulted in a marked increase in the percentage of craters visualized. We cannot, however, say 'No crater, no ulcer.' Where the mucosal defect is seen we know we are on safe ground. When it is not seen we may still make the diagnosis on the basis of the typical deformity associated with a typical ulcer history.

Cancer—When a constant filling defect is found in fluoroscopy or x-rays of the stomach the presumptive diagnosis is carcinoma. Actually there are many other types of space-occupying lesions, including benign tumors and bezoars. These at times have features which distinguish them from the polypoid carcinomas they imitate, e.g., absence of lobulations, fissures and ulcerations. Here again the spot film is of great benefit, although in this type of growth gastroscopy gives more information. The use of the spot film in detecting gastric lesions is shown in Figure 96, multiple polyps of the gastric mucosa are demonstrated which are not seen in routine films.

There is usually little difficulty, except in the very early stages, in diagnosing the infiltrative type of cancer. This lesion results in an irregularity which is constantly found on serial observations, is stiff 'moth-eaten,' and fails to transmit peristalsis smoothly. The lag in peristalsis is an important sign when present, but its absence cannot be completely relied upon as an indication of a normal stomach.

The lesions which offer the most difficulty are those in the antrum and some ulcers on the anterior and posterior walls of the stomach. Antral lesions may be caused by cancer, benign gastric ulcer, duodenal ulcer with antral spasm, hypertrophy of the pyloric muscle, hypertrophic gastritis and syphilis.¹⁰ In some cases one can only hazard a guess as to the nature of the disease associated with a prepyloric deformity. Repeated roentgenologic observations may help. Gastroscopy frequently helps. Exploratory laparotomy and even subtotal gastric resection may occasionally be necessary to rule out cancer.

Benign and Malignant Ulcers.—I do not propose to discuss the question of malignant degeneration in benign gastric ulcer. This has been ably done by Palmer¹¹ and I believe, with him, that such a change has yet to be proved. The important point is to distinguish benign ulcers from malignant ulcers. There are several radiological features that are helpful. Most malignant ulcers are larger than benign ones, but in the individual case this point is of no help, as all of us have seen tremendous

ulcers which were proved benign by operation, as well as very small ulcers which were highly malignant. The location of the niche is important only if on the greater curvature, where benign lesions rarely occur.

The significant feature of a benign ulcer is smoothness of outline. The adjacent rugae are usually thick and stand out from the back-

Fig 96—*A*, Roentgenogram of the stomach of a 50 year old white woman with recurrent epigastric distress and vomiting for several years. The x-ray examination, performed at an excellent laboratory, did not reveal the source of the symptoms. *B*, Spot film of same patient with compression of the stomach, showing multiple gastric polyps. This film was taken after the polyps, together with severe superficial gastritis, had been discovered by gastroscopy.

ground, converging toward the niche. Frequently there is associated spasm, resulting in the "hour-glass" stomach. Tenderness to pressure is present but is of less value in distinction. The malignant ulcer will not show the above characteristics, and in addition may reveal the "meniscus" sign first described by Carmen over twenty years ago. This sign

depends on the fact that a malignant ulcer lies in the approximate center of a raised area, the tumor. Hence a tumefied border, the halo or meniscus, is seen encircling the crater. The convexity of the meniscus, originally emphasized by Carmen, is probably not important,¹² but the intraluminal situation of the crater is essential, i.e., it does not project beyond the normal borders of the stomach but into the tumor itself.

GASTROSCOPY

In the few short years since its popularization in this country by Schindler, gastroscopy has proved its value beyond question. Now that the initial scepticism of the many and subsequent enthusiasm of the few have been tempered by experience it is possible to evaluate the place of gastroscopy in diagnosis. The limitations of gastroscopy are well delineated. It is not in rivalry with the x-ray examination, and never can be, because of these limitations. It should be regarded only as an adjunct to roentgenology.

Gastroscopy is safe. With adequate preparation it is not uncomfortable, many patients preferring it to the introduction of the small tube for gastric analysis. In the hands of even a moderately experienced gastroenterologist the chance of injury, provided the known contraindications are observed, is negligible. A few years ago Schindler found by means of a questionnaire sent to all men known to do gastroscopy that in 22,351 examinations there had occurred ten perforations, with one fatality. Five of the perforations were attributed to the rubber sponge tip, since that time largely discarded.¹³ I feel sure that a questionnaire circulated at the present time would show the percentage of accidents still smaller.

Gastroscopy, of course, should not be done when disease of the esophagus exists. A preliminary fluoroscopic observation of a barium swallow should be done if the history suggests any difficulty in deglutition, or if any trouble is experienced in passing the Ewald tube. The examination should preferably not be attempted at all with marked curvature or arthritis of the cervical or dorsal spine, with intractable cough or dyspnea, with aortic aneurysms or mediastinal tumor displacing the esophagus, or with severe heart disease.¹⁴ In many of these cases gastroscopy can be done successfully, but a risk will be taken which could be justified only if the information to be obtained were absolutely essential. Another type of patient who had best be left alone is the person who is too apprehensive to be cooperative.

The limitation of the gastroscopic examination is that only the gastric mucosa can be seen, and not all of that. The duodenal cap cannot be observed, the pylorus itself is occasionally hidden, the lesser curvature of the antrum is frequently blocked from view by the overhanging angulus, a strip of posterior surface down which the gastro-scope slides is not visible, nor is the lesser curvature adjacent to the

cardia Despite these blind areas most lesions that can be seen by roentgenologic examination can also be seen by gastroscopy, and not infrequently an ulcer or small tumor may be detected which has evaded radiologic investigation¹⁵

There are several groups of cases in which gastroscopy is of definite value It should be done whenever symptoms are suggestive of gastroduodenal disease, even though x-ray films are negative It may be used to confirm positive roentgenologic findings in the stomach, and to help differentiate between benign and malignant lesions When the findings of the x-ray examination are suggestive of disease, the gastro-scope will provide additional information that may be conclusive

Gastritis—The presence of gastritis, other than by biopsy, can be determined only by gastroscopy Most roentgenologists agree that they cannot with certainty make this diagnosis, although occasionally the hypertrophic form may be suggested by thick folds and nodulations outlined by a small amount of a thick barium mixture¹⁶ There is need, it is true, for better correlation of gastroscopic and pathological interpretation, but sufficient studies have been made to place the gastroscopic diagnosis of gastritis on a firm basis¹⁷ It is to be hoped that the Kenamore biopsy forceps will be further improved so that bits of mucosa can readily be taken for pathological confirmation of the gastroscopic impression¹⁸ Another method which will make for greater unanimity of interpretation is gastrophotography, which is now becoming practical¹⁹ When color photographs of abnormal mucosae are commonly published it will quickly be determined whether various observers are talking about the same thing

Gastritis has been classified in various ways Most gastroscopists in this country adhere to the Schindler classification, which divides the inflammatory changes into superficial, hypertrophic and atrophic²⁰ There is essential agreement concerning the differential diagnosis of these forms, as evidenced by the approximately equal percentage of cases found in several large published series It appears, however, that the superficial and hypertrophic forms, in their lesser degrees of severity, may be confused.²¹

Superficial gastritis is believed to be present when the mucosa appears redder than normal, is edematous and shows patches of adherent exudate Small erosions and hemorrhagic spots are not uncommon

The diagnosis of hypertrophic gastritis is based on the finding of a dull, slightly swollen mucosa, lacking the usual highlights, with a nodular "cobblestone" or vermiform appearance The nodes at times may be large enough to resemble true polyps, and have a loose spongy character Small erosions and ulcerations are common

In atrophic gastritis the surface has a grayish color, the folds are few, and the branching network of blood vessels is visible due to thinning of the mucosa This is a picture which can hardly be mistaken Although some gastroscopists believe that excessive inflation of the

stomach with air may cause the blood vessels to be seen, the majority are not of this opinion.² Atrophy of slight degree, as with the other types, may be overlooked by the inexperienced.

Cancer—A typical polypoid malignancy is simple to identify through the gastroscope, although the distinction between carcinoma, sarcoma and other neoplasms may not be possible. The cancer appears as a necrotic mass projecting into the lumen. The limits of the growth and its blending into normal mucosa can usually be made out, and its extent may be found to be much greater than it appeared in the x-ray film. In any series of cases studied by both the x-ray and gastroscopic examinations there will be some cancers which can be seen by one method and not the other, which is the best possible argument for subjecting a patient with a suggestive history to both observations.

One of the chief advantages of the gastroscopic examination is the ability to elucidate the nature of a prepyloric narrowing found by the roentgenologist. As stated earlier, such a deformity may be caused by a variety of conditions, including simple spasm. In many such cases the entire antrum is well visualized gastroscopically, no mucosal abnormality is seen, and the patient is saved from an exploratory laparotomy. Or a simple hypertrophic gastritis may be found to account for the narrowing. However, one of the most difficult problems in gastroscopy is to differentiate a severe antral hypertrophic gastritis from a diffusely infiltrating cancer. In an occasional patient it may even be necessary to subject the patient to partial gastric resection because of the probability of cancer which neither the x-ray nor gastroscopic examinations can rule out. It should be emphasized nevertheless, that in the great majority of patients showing antral deformities an accurate diagnosis can be made by gastroscopy or at least the danger of intrinsic cancer dispelled.

Ulcer—Most gastric ulcers can be seen by gastroscopy, since they usually occur in the posterior wall near the lesser curvature above the angulus. As with carcinoma, both roentgenology and gastroscopy should be utilized, since some ulcerations are visible only by one or the other of these examinations. When an ulcer is directly visualized its course is best followed by repeated endoscopic observations, for it will be found present some days or weeks after it can no longer be seen by the x-ray examination. Duodenal ulcers, of course are detectable only by roentgenology.

Characteristically a benign ulcer is seen as a sharply punched out area with a clean gray or white base, or if penetrating deeply, as a black hole. The surrounding mucosa converges in folds toward the ulcer, may be red and edematous and slightly undermined, if no accompanying gastritis is present. Or it may show the changes diagnostic of superficial or hypertrophic gastritis, particularly if pyloric obstruction is present as a complication of the ulcer.²² Tiny mucosal hemorrhages and brown pigment spots may be present, without gastritis.

Benign and Malignant Ulcers—Some authors have urged that all gastric ulcers be treated surgically on the basis that accurate distinction between benignity and malignancy cannot be made²³ It is true that occasionally the gastroscopist may be undecided after several observations, and then exploration should of course be recommended Rarely he may be mistaken But the mortality of major gastric surgery in most medical centers is certainly greater than the percentage of error by the experienced gastroscopist

There are a number of signs which have been found of value in indicating the malignant nature of an ulcer Of these perhaps the most important is blending of the ulcer floor with its wall²⁴ Even though most of the ulcer margin is sharp, if at one point it is not clear-cut a strong suspicion of cancer must be entertained Irregular nodes within the ulcer floor or in the adjacent mucosa, ulcerations in the wall immediately surrounding the ulcer, and bleeding of the ulcer edge are additional evidences of malignancy The location may be helpful, as benign ulcers rarely occur in the antrum close to the greater curvature, or involve the pylorus There are usually no converging folds in malignant ulcer

In addition to the typical punched-out character of the benign ulcer, Schindler feels that the presence of pigment spots and small mucosal hemorrhages away from the niche are evidence of benignity Henning, a pioneer European gastroscopist, has called attention to an arch-shaped deformity of the angulus as due to benign ulcer on the lesser curvature of the antrum, pulled up out of sight and hidden by the angulus This sign is of value mainly in tending to confirm a roentgenologic diagnosis

Gastrointestinal Allergy—Before closing this discussion mention should be made of gastroscopic confirmation of gastrointestinal allergy, a disorder which may mimic gastroduodenal disease Pollard and Stuart²⁵ have reported the changes seen through the gastroscope following the introduction of the suspected food These were hyperemia of the mucosa, edema, diminished peristalsis and the outpouring of quantities of grayish mucus, all involving mainly the lower one-third of the stomach Further study along this line should help greatly in understanding and diagnosing gastrointestinal allergy

SUMMARY

Recent developments in gastroenterology have made the diagnosis of gastroduodenal disease extremely accurate A careful history is important in determining what, if any, aids in diagnosis should be used Roentgenologic observation, particularly with the use of the spot film is the most important single additional examination Gastroscopy, however, is essential for the detection of gastritis, and is valuable in confirming positive roentgenologic findings, in differentiating benign and malignant lesions of the stomach, in further elucidating suspicious x-ray

findings, and in discovering an occasional ulcer or neoplasm that the x-ray examination has missed

DIAGNOSIS AND TREATMENT OF PLEURAL EFFUSIONS

ALFRED GOLDMAN, M D , F A C P *

FLUID in the pleural cavity is a common clinical finding as a complication of both pulmonary and extrapulmonary disease. Rarely does it represent any primary lesion of the pleura. Usually the interpretation of the fluid is simple, as in the effusion occurring during the course of a pneumonia or an obvious pulmonary tuberculosis. Often, however, the diagnosis may be difficult and requires careful study of the fluid for a correct interpretation of the underlying disease. It is the purpose of this discussion to group together the various practical methods used in the study of effusions with particular reference to the gross and microscopic characteristics, and to outline the treatment of the important types. All known pleural fluids will be included. Symptoms and signs will not be discussed as these are common knowledge to all. The subject matter will be taken up under the headings of (1) thoracentesis, (2) clinical pathology of the fluid, (3) classification of pleural fluids and (4) treatment of important types.

THORACENTESIS

The final diagnosis in the study of pleural fluids lies in the examination of the fluid itself. The *site of aspiration* should be carefully selected by physical signs and x-ray examination. This is especially important in interlobar, mediastinal and diaphragmatic collections of fluid, when it becomes necessary to take both upright and anteroposterior and lateral plates of the chest. Plates taken in the prone position are often misleading, as the fluid may spread over the entire lung field in this position. It has been generally assumed that pleural fluids do not move with change in position except in the presence of a complicating pneumothorax. Rugler¹ has shown, however, that pleural transudates and exudates of recent origin before adhesions have formed will shift considerably with change of position. The patient should be tapped while lying on his sound side. At times it may be necessary to have the patient in the sitting position, particularly in the presence of a hydro-pneumothorax or in cardiac decompensation.

The skin is prepared with iodine and alcohol, and an intracutaneous bleb is made using a fine hypodermic needle and 1 per cent novocaine. Then the deeper tissues are infiltrated down to the pleura with a No. 21 needle. Aspiration is then carried out using a 50 cc syringe and a

From the Department of Internal Medicine, Washington University School of Medicine, St. Louis, Missouri.

* Assistant Professor of Clinical Medicine, Washington University School of Medicine.

long needle, size 18 to 14. While suction devices such as a Potain apparatus may be used, they are undesirable, as too rapid evacuation of fluid may produce chest pain, cough, syncope or even pulmonary edema. In handling large amounts of fluid, a two-way stopcock for withdrawal of the fluid into the syringe and then emptying it into the container should be used.

If untoward symptoms occur, aspiration is either discontinued or introduction of air into the pleural cavity, either with the syringe or preferably with a pneumothorax machine through a cotton filter, will usually stop the symptoms and aspiration may then be continued. The amount of air used should be about one-third of the fluid removed. Sometimes the introduction of air is desirable for diagnostic and therapeutic purposes, in which case it should be done at the time of aspiration. A pneumothorax is often of value in differentiating between pulmonary, mediastinal and thoracic wall lesions.

CLINICAL PATHOLOGY OF PLEURAL FLUIDS

A. Physical and Chemical Characteristics—1 *Gross*—Fluids may be classified by their gross appearance as (a) serous or serofibrinous, (b) seropurulent or purulent, (c) hemorrhagic, (d) chylous or pseudo-chylous, (e) cholesterous, (f) bile-stained, or (g) combinations of any of the above.

2 *Specific Gravity*—The specific gravity is of particular importance in the nonpurulent effusions. It at once classifies fluids into transudates or edema fluids, and exudates or inflammatory fluids. In general, the transudate has a specific gravity below 1.015, the exudate above 1.018, the malignant effusion about 1.017.

3 *Chemical Studies*—These are usually of little practical importance. In general, the protein content is roughly in direct proportion to the specific gravity. A specific gravity of 1.012 means less than 2 per cent protein (transudate), while a specific gravity of 1.018 means more than 4 per cent protein (exudate). Simple transudates usually do not coagulate while exudates generally do. A rough but simple estimate of the protein may be made with the Esbach albuminometer. The pleural fluid should be diluted 1 to 10 with distilled water. Estimation of the sugar content of the fluid has some value in the study of the effusions following artificial pneumothorax. A figure of over 70 mg per 100 cc. is a favorable sign indicating sterility, while one of under 50 mg indicates the presence of tubercle bacilli and a subsequent empyema formation (Nassau²).

4 *Cytology*—The study of the cells in pleural fluids is of particular importance in the nonpurulent effusions. The fluid should be citrated to prevent clotting, centrifuged and a portion of the sediment spread on a slide, allowed to dry in air, then stained with Wright's stain. In every undiagnosed case where there is a possibility of malignancy, the *section sediment method of Mandelbaum*³ is an absolute prerequisite.

as tumor cells can be demonstrated in the majority of effusions due to a malignancy. The original method is as follows:

The fluid is placed in a large Erlenmeyer flask and allowed to stand over night in an ice-box. The supernatant fluid is decanted and the sediment poured in a large centrifuge tube and centrifuged for at least twenty minutes at moderate speed. The supernatant fluid is again decanted and the sediment hardened with a solution of 10 per cent formaldehyde or Zenker's fluid for twenty-four hours. The fixed sediment is then treated as ordinary tissue by running through alcohols, embedding in paraffin and staining with hematoxylin-eosin. The final sediment is a little conical button, which is cut from the above down, so as to include all cellular elements. *Foot's*⁴ *modification* is the addition of glacial acetic acid to bring the acid percentage to 2 per cent which prevents coagulation. The advantage of the section-sediment is that the cells in a large amount of fluid may be studied in their natural relationship to each other. The method is an excellent one to demonstrate all types of cells, as well as such unusual lesions as actinomycosis.

The following cells may be seen in pleural fluids:

1 *Polymorphonuclear Leukocytes*—These obviously predominate in all pyogenic infections.

2 *Lymphocytes*—A high proportion of lymphocytes is typical of tuberculosis. However, they are also present in large numbers in malignant effusions, tularemia and the effusion of Meigs' syndrome.

3 *Red Blood Cells*—These are present to some degree in most pleural fluids. Grossly bloody fluids may be classified as follows:

(a) *Hemothorax*. This is a mechanical bleeding into the pleural cavity due to the following causes:

1 Trauma of the chest

2 Rupture of an aneurysm or erosion of an intercostal vessel

3 Spontaneous idiopathic hemopneumothorax. This is an unusual disease occurring suddenly in young healthy males, probably due to the rupture of subpleural blebs and tearing of adhesions.

(b) *True hemorrhagic effusions*. These may be serosanguineous or frankly bloody. Approximately two thirds of all hemorrhagic effusions are due to malignant tumors (Berliner⁵). Next in frequency follows inflammatory lesions of miscellaneous types, tuberculosis and pulmonary infarction. Occasional rare causes are heart disease, rheumatic fever, blood dyscrasias such as hemophilia, purpura, scurvy and severe anemia, Meigs' syndrome, snake bite and heparin.

4 *Mesothelial Cells*—These are large cells with abundant cytoplasm and pale-staining nuclei. They are characteristic of the cardiac transudates. At times the cells may be swollen, degenerated and vacuolated.

and may be confused with tumor cells. Mitotic figures may even be present in nonmalignant effusions.

5 Eosinophils—It is not uncommon to find eosinophils in pleural fluids. They have been found in the following lesions: (a) hemothorax, especially during the clearing stage, (b) pneumonia, particularly in the recurrent pneumonias of the asthmatic, (c) tuberculosis, (d) following artificial pneumothorax for tuberculosis, (e) effusions due to malignant tumors, (f) hydatid disease, (g) pulmonary infarcts, (h) heart disease, (i) nephritis, (j) repeated pleural punctures, and (k) intrapleural injections of saline, gold salts or olive oil. The significance of eosinophils in such a wide array of diseases is not known. There is usually no relationship between the percentage of eosinophils in the fluid and that in the blood.

6 Tumor Cells—By the Mandelbaum method previously described, tumor cells can be demonstrated in approximately 60 per cent of effusions due to malignant tumors. The cells appear in the section in two forms: (a) Fragments of tumor tissue showing glandular or pseudoglandular arrangements or clumps of tumor cells. These can be easily recognized. (b) Isolated tumor cells. These are large atypical cells with deeply staining eccentric nuclei, often with mitotic figures, the cells standing out conspicuously around the other cells in the sediment. They may be confused with degenerated endothelial cells. *Positive diagnosis on the basis of isolated tumor cells should be made only by the expert pathologist.*

C Bacteriology—All fluids, whether serous or purulent, should be studied bacteriologically. The empyema following a pneumonia may start as a clear effusion from which the pneumococcus or streptococcus may be obtained. Serous and serofibrinous exudates not due to any obvious cause are tuberculous in at least 80 per cent of the cases. Tubercle bacilli may be found on direct smear or in a larger number of cases by culture and guinea-pig inoculation, an essential procedure in all doubtful cases. Even when organisms cannot be demonstrated, the effusion should be considered as tuberculous in origin unless proved otherwise. Tularemia is an important cause of serous effusions, as 14 per cent (Blackford and Case⁴) of tularemic pneumonias have pleural effusions which may persist for months. *B. tularensis* can be recovered from the fluid by special cultural methods.

The most frequent cause of purulent effusions are the pyogenic organisms with the pneumococcus first, streptococcus next and staphylococcus third in the order of their frequency. Practically every form of pyogenic organisms has been recovered from empyemas. It must be emphasized that 5 to 10 per cent of all chronic empyemas are tuberculous. In the secondarily infected tuberculous empyema, mistakes are often made and tuberculosis is overlooked. A pyopneumothorax should always suggest its possibility. Another important cause of empyema is fungus infection which usually produces thick pus. The

most common fungus disease found is actinomycosis, then blastomycosis and occasionally streptothricosis. *Coccidioides immitis* has also been recovered from pleural fluids. On occasion the section-sediment has demonstrated fungi when the bacteriological examination was negative.

D Serology—Serological tests of pleural fluids are sometimes of value. In tularemia the fluid shows a high titer of agglutinins for *B. tularensis*. The Wassermann reaction may be positive in the occasional case of luetic effusion. Complement-fixation tests for tuberculosis are advocated by some and are said to be positive in the majority of tuberculous effusions (Ogawa⁷).

CLASSIFICATION OF PLEURAL FLUIDS

A *Noninflammatory Fluids—Transudates*

- 1 Hydrothorax
- 2 Hemothorax
- 3 Chylothorax
- 4 Cholesterothorax

B *Inflammatory Effusions—Exudates*

- 1 Pyogenic empyema
- 2 Tuberculosis
- 3 Mycotic infections
- 4 Parasitic infections
 - (a) *Echinococcus* cysts of pleura
 - (b) Pulmonary distomiasis (lung fluke)
 - (c) Ameba
- 5 Tularemia
- 6 Rheumatic fever
- 7 Disseminated lupus erythematosus
- 8 Polyserositis
- 9 Specific diseases rarely associated with pleural effusions

C *Effusions Due to Malignant Tumors of the Pleura*

D *Effusions of Meigs' Syndrome*

A Noninflammatory Fluids—1 Hydrothorax—This is a transudation of serous fluid into the pleural cavity. The fluid is clear, straw-colored, has a specific gravity below 1.015, has very little protein and few cells and is sterile. The most common causes of hydrothorax are (a) cardiac disease of all types with associated heart failure, (b) renal disease, (c) cirrhosis of the liver, (d) Banti's disease, (e) local venous obstruction by mediastinal tumors, aneurysms, and the like, and (f) terminal events in pernicious anemia, leukemia.

2 Hemothorax—The causes of hemothorax have already been discussed under cytology.

3 Chylothorax—This is an accumulation of milky fluid in the pleural cavity.

(a) *True chylous effusions*—The percentage of fat is high, creams on standing, clears on shaking with a fat solvent, contains many fat globules stainable with fat stains. The following are the important causes:

- 1 Trauma to thoracic duct
- 2 New growth or glands outside the duct or within the duct.
- 3 Parasitic invasions, *Filaria*, *Trichina*
- + Thrombosis of left subclavian vein
- o Perforating lymphangitis

(b) *Chyliform effusions* The chylous appearance is due to fat droplets from degenerating cells. The globules are smaller. It is caused chiefly by carcinoma or tuberculosis.

(c) *Pseudochylous effusions* The fluid is milky but contains no fat globules. The cause of the milky fluid has been ascribed to a lecithin globulin (Wallis and Scholberg⁸) and also to calcium phosphate (West⁹). Blankenhorn¹⁰ thinks that all the cases are due to very fine emulsified fat.

+ *Cholesterothorax*—This is a rare type of effusion containing large numbers of cholesterol crystals which give the fluid a peculiar opalescent, bright, glistening appearance. It has been most commonly found in long-standing tuberculous effusions. The pleura is found to be very thick, acting as an impermeable membrane. Blood cholesterol is not increased in these cases.

B Inflammatory Effusions—Exudates.—1 *Pyogenic Empyema*—*Empyema* is usually secondary to a pneumonia or a suppurative lung disease. It may also occur as a direct extension from a pericarditis, through the diaphragm from an abdominal abscess and from penetrating wounds of the chest wall. The pus is usually creamy yellow. The pus from different types of empyema varies sufficiently to be of some diagnostic value. While the pneumococcus empyema starts off as a serofibrinous exudate, it rapidly thickens up to a creamy-yellow pus. The streptococcus exudate is thinner, being characteristically like thin pea soup. It is slower in thickening up and when it does, it is a thick whitish-green pus. When the pus is dark brown and fetid, there is usually an associated mixed infection, often with anaerobes. Rarely gas bacillus may be present and bubbles found in the pleural fluid.

2 *Tuberculosis*—Every case of pulmonary effusion which cannot be explained on any other basis should be considered as tuberculous. The vast majority of so-called primary or idiopathic pleural effusions are due to the tubercle bacillus. Unfortunately, the organism can only be found in about 30 per cent of the serous cases on direct smear, hence the importance of culture and guinea-pig inoculation. All tuberculous fluids have a high specific gravity above 1.020 and coagulate rapidly.

Both the spontaneous effusions and those occurring after artificial pneumothorax may be classified as (a) nonpurulent and (b) purulent, and the latter subdivided into (1) true tuberculous empyema and (2) mixed infection. The nonpurulent effusions usually start as clear straw-colored to amber fluid with more or less fibrin. Varying amounts of blood may be present which may give the fluid a hemorrhagic appear-

ance Tubercle bacilli may be absent or present in small numbers The fluid may spontaneously disappear The lymphocyte is the predominant cell The serous effusion may go on to become an empyema and must therefore be watched carefully

The tuberculous empyema fluid is purulent in appearance but thin and yellowish and flows easily While many lymphocytes are usually present, polymorphonuclears may predominate, especially in the cases following spontaneous pneumothorax Tubercle bacilli can readily be found

In the mixed infection types, the fluid takes on the appearance of pyogenic empyema becoming thicker and containing many pus cells

3 *Mycotic Infections*—Fungus infections rarely produce massive pleural effusions However, the pulmonary lesions may spread to the pleura where abscesses form and on aspiration the fungi may be found when cultured The section-sediment as mentioned previously may show the organisms Pleural lesions due to fungi have been found in (a) actinomycosis, (b) streptothricosis, (c) blastomycosis, (d) sporothricosis and (e) primary coccidioidal infections and coccidioidal granuloma

4 *Parasitic Infections*—(a) Echinococcus cysts of the lung may rupture into the pleura or may form in the pleura The withdrawn fluid contains characteristic hooklets The disease is rare in this country

(b) Pulmonary distomiasis (lung fluke) is common in Japan and China It is occasionally associated with a pleural effusion

(c) Amebic infection of the pleura may occur as a result of rupture of amebic liver abscess through the diaphragm into the pleural cavity The resultant abscess usually ruptures directly into the lung and may be found in the sputum The pleural effusion which may result is first serofibrinous and sterile but may become purulent by secondary infection The cells are usually polymorphonuclears and eosinophils with few lymphocytes Amebae may be found in the fluid

5 *Tularemia*—Pleural effusion is common in pulmonary and typhoid tularemia It appears later in the disease, sometimes four weeks after the onset It may persist for many months and therefore is easily confused with tuberculosis Thirteen of ninety-five patients reported by Blackford and Case⁶ had pleural effusion The fluid is slightly turbid, yellowish, with a specific gravity above 1.017 The total cell count is not high and lymphocytes predominate The diagnosis can be made by recovery by *B. tularensis* from the fluid, by agglutination titer of the fluid and patient's blood, or by inoculation of a guinea pig The latter should be done with care as there is a high incidence of tularemia in laboratory workers

6 *Rheumatic Fever*—Pleural effusion is not uncommon in rheumatic fever It may occur as a primary manifestation, often in association with pericarditis, as a result of pulmonary infarction, pneumonia

or cardiac insufficiency. The fluid is usually clear, slightly turbid and straw-colored. Red blood cells may be present in sufficient numbers to give it a sanguineous appearance. It clots quickly, contains varying numbers of polymorphonuclears, lymphocytes, endothelial cells and is sterile on culture. It is rarely present in large quantities.

7 *Lupus Erythematosus Disseminata*—In this disease there is a tendency to recurrent serositis. The pleural effusion that may occur has the characteristics of a serofibrinous exudate.

8 *Polyserositis*—The pleural effusion in polyserositis is associated with a pericardial and peritoneal effusion. Inasmuch as the usual cause is tuberculosis, the fluid has the characteristics of the serofibrinous effusion seen in tuberculosis.

9 *Specific Diseases* rarely associated with pleural effusions include (a) syphilis, (b) smallpox, (c) anthrax, (d) undulant fever, (e) meningococcus sepsis, (f) typhoid fever, (g) bubonic plague, (h) sarcoidosis and (i) malaria.

C *Effusions Due to Malignant Tumors of the Pleura*—Practically all tumors which invade the pleural and cause effusion are secondary. Occasionally one finds a malignant tumor which suggests a primary endothelioma of the pleura, though many pathologists doubt its existence. The fluid in malignant effusions is either straw-colored serous, serosanguineous or frankly bloody. As already stated, the majority of bloody fluids particularly in the older age group, are due to malignancy. However, not more than half of malignant tumor fluids are bloody. The specific gravity averages 1.017. Tumor cells can be demonstrated in 60 per cent of all cases by the Mandelbaum method. If one excludes the effusions due to pressure on mediastinal vessels, the percentage is still higher. Such effusions are in reality transudates. Metastatic tumorous effusions arising from tissues other than the lungs almost invariably will show tumor cells.

D *Effusion of Meigs' Syndrome*—Meigs' syndrome is given an important heading in spite of its rarity in order to call attention to a very important type of effusion, knowledge of which is relatively recent. Moreover, it is difficult to classify it with any other effusion. The syndrome first reported by Meigs¹¹ in 1937 is that of a benign ovarian fibroma with pleural effusion and ascites. The fluid has the characteristics of a transudate. It is usually clear, straw-colored, rarely hemorrhagic, specific gravity of 1.016 to 1.018, albumin content is low, the cells are few in number and are predominantly lymphocytes. The cause of the effusion is unknown, but the recognition of the syndrome is extremely important as removal of the fibroma is curative of the entire picture. Deaths have occurred in unrecognized and unoperated cases. One must therefore keep the syndrome in mind in all unexplained effusions in the female. Ascites may be so slight as to be overlooked while the pleural fluid may be large in amount.

TREATMENT OF IMPORTANT TYPES OF FLUIDS

A Noninflammatory Fluids—1 *Hydrothorax*—Treatment is directed primarily to the cause of the transudate. If the fluid is small in amount, it may be left to be absorbed spontaneously. If it is large enough to produce symptoms of dyspnea, cyanosis or displacement of the mediastinum, it should be aspirated.

2 *Hemothorax*—The essential treatment is early aspiration without air replacement. Unless there has been sufficient bleeding to produce pressure symptoms, aspiration is delayed to the second or third day following the hemorrhage. The blood is removed daily by aspiration until the pleura is dry. By limiting the amount of fluid removed to about 500 cc reactions are usually avoided. If they should occur, aspiration should be discontinued. Occasionally it may become necessary to introduce air if there is evidence of a recurrent hemorrhage of the lung or to counteract the feeling of tightness or pain in the chest which may result from aspiration. Massive clot formation occurs in about 5 per cent of cases (Carter and DeBakey¹²). Aspiration in such cases is difficult. The presence of large clots prevents the lung from expanding and would result in extensive fibrosis of the pleura and atelectasis of the lung. If, after several weeks, lung expansion has not occurred, the clots should be removed by operation sometimes with decortication of the lung and the chest closed up tight.

3 *Chylothorax*—Treatment is directed to the primary cause of the disease. Aspiration may be necessary because of pressure symptoms. Smith and Wolner¹³ advocate the intravenous injection of the chyle back into the patient.

4 *Cholesterothorax*—Aspiration is done to clear out the pleural cavity in an attempt to assist expansion of the lung. The pleura usually remains very thick, inasmuch as a prerequisite of the formation of the crystals is a long-standing effusion, usually of several years' duration.

B Inflammatory Fluids—1 *Pyogenic Empyema*—Repeated aspiration of the pus occasionally cures an empyema, particularly in the child. Continuous closed drainage as described by Mazingo¹⁴ and Hart¹⁵ may be used. While many patients have been cured by closed drainage, there are many objections to the method and it should be used only when there is some contraindication to open drainage. Thoracotomy with removal of a portion of a rib is the procedure of choice. The most important principle in the surgical treatment of empyema is the selection of the time of operation. This should be done when the pus has become thick, as by this time adhesions have formed and usually the pneumonia has quieted down.

Penicillin is proving an invaluable aid in the treatment of the empyema due to the pneumococcus, streptococcus and staphylococcus. Daily instillations of 25,000 to 50,000 units directly into the pleural cavity are made. Prior to the injection of the penicillin, the pus is aspirated and the pleural cavity irrigated with normal saline solution.

In a few days the pus becomes sterile and thin, following which daily aspirations should be made. Thickening of the exudate with accumulation of much fibrinous material may necessitate thoracotomy. Apparently some cases of coccal empyema may be cured by penicillin, without surgical drainage (Tillet, Cambier and McCormack¹⁰)

2 *Tuberculosis*—All cases of tuberculous pleural effusions should be treated by the general methods of treatment of tuberculosis, namely, bed rest, fresh air and adequate diet. Small nonpurulent fluids will spontaneously absorb. Large accumulations must be removed and careful x-ray study of the lungs made. If there is obvious pulmonary involvement, air should be introduced and a pneumothorax maintained. If the lungs are not visibly involved, aspiration alone is indicated. Rest in bed should be maintained for several weeks after all fluid has disappeared and then the patient may be allowed up on graduated exercise. Obviously, in those cases in which there is considerable involvement of the lung, bed rest may have to be maintained for a much longer period.

The pure tuberculous empyema is treated first of all by repeated aspiration. Irrigation of the pleural cavity with normal saline or Dakin's solution is usually advisable. This can be done with a three-way stopcock by which one can aspirate pus, evacuate it, replace with air, and then wash out with saline (Matson¹⁷). This is done in 100-cc. amounts with final complete emptying of the pleural cavity and replacing with air.

If repeated irrigations do not control the empyema, the next step is the use of oleothorax. The oil used is gomenol either in paraffin oil or olive oil. Gomenol is a volatile oil which inhibits the growth of tubercle bacilli in 5 per cent concentration and staphylococcus in 10 per cent. A pleuropulmonary fistula is a contraindication to its use. This can be determined by the introduction of a few cubic centimeters of a harmless dye such as methylene blue into the pleural cavity following which the patient's sputum will be colored if a fistula is present. The production of an oleothorax is accomplished by repeated aspiration of the pus followed by replacement with 5 per cent gomenolized paraffin oil until the entire cavity is filled with oil. Complete details of the method are given by Matson¹⁷. In the majority of cases, thoracoplasty becomes necessary to control the empyema. This is done to completely obliterate the pleural space and thus get rid of the effusion.

In the mixed infection type, there is a complication of a pyogenic and tuberculous empyema. One may try a disinfection type of oleothorax using 10 per cent gomenolized olive oil.¹⁷ If this fails, thoracotomy should be done first to drain the secondary infection, to be followed later by thoracoplasty.

3 *Fungus Infections*—Fungus infections are treated by wide surgical drainage and excision of diseased tissue. Large doses of potassium iodide are helpful.

Treatment of the remaining types of inflammatory effusions consist primarily of the treatment of the underlying disease and requires no special consideration

C Effusions Due to Malignant Tumors—These present a hopeless prognosis. Repeated aspiration may give the patient temporary relief. X-ray therapy is valueless. One must be certain that the effusion present in association with a tumor of the lung is caused by metastasis to the pleura, as such an effusion may be benign.

D Effusion Due to Meigs' Syndrome—In this rare and easily overlooked disease, removal of the ovarian fibroma results in a brilliant cure. The patient should be first prepared by aspiration of the pleural effusion.

SUMMARY

1 The important diagnostic methods in the study of pleural fluids are outlined. The most valuable procedures in the nonpurulent effusions are the determination of the specific gravity and the study of the cells in the fluid. The latter is best carried out by the section-sediment method of Mandelbaum. The significance of the various cells found in pleural fluids is given in detail. The bacteriology of the purulent effusions readily determines the underlying disease. Tuberculosis must always be kept in mind as a possible cause. Fungus infections occasionally invade the pleura and are readily overlooked unless specifically investigated.

2 All known pleural fluids are classified. Particular emphasis is laid on the effusions due to tuberculosis, tularemia, and Meigs' syndrome.

3 Treatment of the important types of pleural effusions is given.

DIFFERENTIAL DIAGNOSIS OF PRECORDIAL PAIN

JULIUS JENSEN M.D., PH.D. (Med.), M.R.C.S. (Eng.)
L.R.C.P. (London)*

With improving differential diagnosis the study of precordial pain becomes increasingly complicated. Our recent enthusiasm about "coronary pain" has for a while led us to overlook many conditions which now emerge as problems of differential diagnosis. Many patients seen in cardiological consultation practice do not have heart disease although their symptoms at one time or another may have been quite deceptive. In 1935 Herrick¹ listed no less than twenty-eight different conditions which had been mistaken for coronary thrombosis. Special papers have described many aspects of the problem, but because of its importance, it was thought worth while to review as a whole the various mechanisms of precordial pain and the various diagnostic difficulties involved in each one.

MYOCARDIAL ANOXEMIA

We accept the concept that anoxemia of the myocardium is painful and is the cause of most pain arising from coronary disease, be it "angina pectoris of effort and of emotional tension," infarction of the myocardium or the less easily defined "coronary insufficiency."² We also agree that a similar mechanism probably is effective in a number of conditions in which the coronaries may be functionally intact. This would be feasible if the blood pressure for any reason is lowered to a point where it is unable to maintain an adequate supply of blood in the coronary system. If coronary disease interferes with arterial function such pain is, of course, brought on more easily. Anemia itself is not necessarily a cause of precordial pain, but it may facilitate its production by other factors. Sometimes lowering of the blood pressure causes precordial pain by an indirect mechanism, it favors thrombus formation in arteries which are atherosclerotic. This is the mechanism seen after operations,³ and also after drinking ice water⁴ which presumably leads to cooling and dilation of the coronaries near the esophagus and consequently to slowing of the blood stream with thrombosis. The low blood pressure may be at least partly responsible when hypotensive, hyposthenic persons complain of precordial pain on effort. Another similar cause of pain through inefficient blood flow

From the Department of Internal Medicine Washington University St. Louis, Missouri

Assistant Professor of Clinical Medicine, Washington University School of Medicine. Assistant Physician Barnes and St. Luke's Hospitals. Cardiac Consultant, St. Louis City and St. Louis County Hospitals

is seen in marked tachycardia or in marked bradycardia. When tachycardia reaches the critical stage the diastolic phase may become too short for ventricular filling. Consequently, the stroke volume is diminished and the myocardial nutrition suffers. The resulting pain has repeatedly been confused with that of myocardial infarction. Anoxemia of hypercyanosis of mitral stenosis⁵ may cause a pain which in all respects resembles that of myocardial infarction.

Myocardial nutrition may be impaired by actual *blocking of the coronary arteries*. This may be organic or, possibly, functional. Organic blocking of the coronary arteries may occur at their orifices, which may be blocked by vegetations or by syphilitic changes of the aorta. Syphilis of the coronaries themselves has been described but is rare. The typical coronary atherosclerosis and arteriosclerosis occurring along the course of the arteries gives rise to the classical angina pectoris of effort and of emotion. This is almost certainly a pain of relative ischemia brought about by failure of the coronary circulation to dilate sufficiently to carry the increased load of blood required for increased cardiac work. It is readily relieved by rest. The precordial pain of similar distribution in patients with known coronary disease, but occurring at rest, even awakening the patient from his sleep, is called pain of coronary insufficiency, which it almost certainly is, although the exact mechanism of its production is obscure. In its milder forms it may closely resemble the sensations of "heart consciousness" or "neurocirculatory asthenia." Perhaps in some cases the two conditions overlap.

It is thought that *spasm of the wall of the coronary arteries* can produce a similar pain, but that has not been definitely proved. The coronary arteries do possess vasoconstrictor nerves, and we know that smooth musculature generally is influenced by emotions. Striking examples of this are "spastic colitis" and emotional increases of blood pressure. Smooth musculature is almost certainly involved in other psychosomatic manifestations. Offhand there is, therefore, no reason why smooth musculature of the coronary arteries should not be involved in precordial pain arising from psychic conflicts.

If this mechanism does exist, it may be coexistent with two other mechanisms of unquestioned reality. One is the precordial pain which, in the presence of established coronary atherosclerosis is produced only by *emotional stress*. It seems almost necessary to assume the presence of some such functional factor when patients complain of pain when they get angry while a whole day's quail-shooting can be accomplished without discomfort.

The other mechanism is marked *lowering of the threshold of pain*. This will presently be discussed, but when severe precordial pain occurs in young hypersensitive persons under emotional strain, and the pain is projected along the very same cutaneous segments which carry the pain of true angina pectoris, it seems entirely likely that a spasm

of the coronary arteries as well as a lowering of the threshold to pain may be involved. Another observation which supports the conception of coronary spasm as a cause of precordial pain is the reflex change which may occur in the electrocardiogram when pain arising from some organ below the diaphragm is referred to the paths along which cardiac pain is generally projected. The simplest explanation of these changes is that the pain being referred to the cardiac nerves causes coronary spasm which in turn is responsible for the myocardial changes (ischemia) which affect the electrocardiogram.

It is, therefore, probable that coronary spasm may cause myocardial pain, and that the pain results primarily through myocardial ischemia. Whether the actual spasm may cause pain as it does for instance in gallstone colic is perhaps too obscure a question to be answered at this time.

SPASM OF SMOOTH MUSCULATURE

While it is not possible to establish that spasm of coronary musculature in itself causes pain there is no question but that spasm of smooth musculature elsewhere in the body may do that and that such pain may be referred to the precordium.^{6, 7}

CASE I—A 65 year old white housewife had been nervous for a year. She had been under a psychiatrist's care in the hospital during April and May, 1943. About May 1, 1944 she began to get spells of pain beginning in the top of the epigastrium, radiating to the back and up the chest into both shoulders and into both arms. There was no known exciting cause they might come on any time of the day or night. On walking she sometimes got an oppressive feeling in the epigastrium. The pain would last forty five to seventy five minutes until she took empirin which relieved it. She suffered from gas and was relieved of her pain if she could pass it. The pain made her walk the floor and doubled her up. She did not vomit. She had indigestion following cheese and "7-Up." Anything eaten at night would give her trouble later on. Altogether she had twenty five attacks when first seen on May 7, 1944. She was referred by an excellent surgeon as a case of heart disease.

The physical examination revealed a well nourished woman with a blood pressure of 156/80 (later 176/82). The heart was normal transverse in position, the aortic shadow was wide and tortuous. The electrocardiogram was normal. The abdomen was slightly tender at the top of the epigastrium, but there was no tenderness over the gallbladder on repeated thorough palpation.

The patient was thought not to have heart disease. A ray of the colon showed spastic sigmoid colitis, for which she was treated. However, the symptoms persisted and became worse and on June 23, 1944 further x ray examination revealed gallbladder disease. Subsequent operation showed gallstones, she was improved following operation, and has had no more attacks.

Numerous similar cases may be found in the literature where they record many diagnostic difficulties and mistakes. Thus papers on the *differential diagnosis between coronary disease and gallbladder disease* have repeatedly appeared^{8, 9} and the problem is far from being solved. The following factors contribute to the diagnostic problem: (1) Although the exact pathogenesis of neither of these conditions is known

an element of disturbed lipid metabolism is involved in both. They are both likely to occur in late middle age in overnourished persons. (2) Both of them are often associated with dyspepsia of varying degrees. (3) If in coronary disease the myocardium becomes insufficient the resulting congestion of the liver may produce pain and tenderness which may suggest gallbladder disease. (4) The pain of gallbladder disease may be referred over the precordium and in its severity (as in our case) may suggest heart attacks. If such patients are electrocardiographed during an attack, the electrocardiogram may show changes which suggest coronary insufficiency. These may clear up when the patient recovers. It remains questionable whether these changes are on an entirely functional basis or whether they reveal an otherwise latent pathologic state of the coronary circulation. (5) Finally, and most confusing is the fact that the two conditions may coexist in the same individual.

Precordial pain arising from heart disease shows an amazing variety in its cutaneous projection, which is difficult to explain. Fibers which have already carried pain due to other causes are predisposed to project heart pain when it occurs. Boas⁹ has made some interesting observations in this field. In a patient with angina pectoris and with an abscessed tooth, the anginal pain would radiate to the affected tooth (Mackenzie). Anginal pain in the neck may be associated with arthritis of the left shoulder, anginal distribution in the lower part of the chest and upper abdomen may be associated with peptic ulcer or gallbladder disease. On the other hand, a patient who has both gallbladder disease and coronary disease may feel pain over the precordium which otherwise has the characteristics of pain arising from gallbladder disease. This brings up the interesting but as yet unanswered question as to whether such location of radiation is a first evidence of coronary disease, so far subclinical. All of these considerations necessitate extreme caution in differential diagnosis in cases presenting unusual features.

DIRECT IRRITATION OF NERVES

Direct irritation of the cutaneous nerves along which cardiac pain is usually projected may produce a clinical picture closely resembling heart disease. The literature contains many such cases. The most common cause of error is *arthritis of the spine*, pinching the nerves.¹¹ This pain may be affected by exercise and may be severe. Whenever pain projected along the thoracic nerves does not sound quite typical of angina pectoris, x-ray examination of the thoracic spine is indicated.

Another less common cause of error is *herpes zoster*, as illustrated in the following case report.

CASE II—The patient, a 63 year old woman, had previously been well except for asthma which was well controlled by various remedies. Her mother died in a heart attack. On the night of September 11, 1944 she developed suddenly a severe pain in the left side of the chest, especially over the upper sternum, and

radiating into the left arm. The pain was very severe and kept her awake most of the night. It was oppressive and at the same time burning in character waxing and waning at times becoming exceedingly severe. The next day she felt better but with the coming night it again increased in severity. She felt compelled to awaken her husband who called their physician at 4 00 A.M. On his arrival the pain had subsided somewhat and the patient looked remarkably well. There was no dyspnea. The blood pressure was 164/86, the heart rate 76 with regular rhythm and the sounds of good quality. The lungs were clear and there was no tenderness anywhere. Because of the distribution and character of the pain it was thought that she had suffered a myocardial infarction and she was admitted to the hospital the following morning. During the next two days she felt well, and slept most of the time. Only once did the pain threaten to return and it was promptly controlled with codeine. The electrocardiogram was normal, temperature, blood count and sedimentation rate remained normal. On the morning of the 15th she was found to have a typical rash of herpes zoster extending over the left chest and down the inside of the left arm.

In this case there is no reason to believe that the patient had heart disease, but cases have been reported (Spillane and White¹²), in which herpes zoster and heart disease have coexisted.

In this connection must be mentioned certain obscure cases of neuralgia of the thoracic nerves which are difficult to explain. Neuralgia, however, should remain a "back to the wall" diagnosis after all other possibilities have been exhausted. Myositis of the muscles of the neck and about the thorax have also been mistaken for heart disease.

IRRITATION OF SEROUS MEMBRANES OF THE CHEST

Mediastinal emphysema,¹³ *inflammation of the serous membranes of the mediastinum, of the pleura and of the pericardium*¹⁴ have all been mistaken for pain of coronary origin, especially myocardial infarction. One difficulty is that myocardial infarction, extending to the surface of the heart, may cause pericarditis. Also, pericarditis may in turn affect the underlying myocardium and the resulting electrocardiographic changes have been mistaken for those of myocardial infarction which they may closely resemble. Only in recent years have the electrocardiographic changes of pericarditis been recognized as having specific features which separate them from those of myocardial infarction. It is not uncommon to see young persons with pain in the chest which was thought to arise from myocardial infarction, but which really was a symptom of pericarditis. Weinstein¹⁵ has recently published a series of cases which emphasize the difficulty involved in differential diagnosis. The difficulty is further complicated by the possibility that acute respiratory streptococcal infections may be associated with rheumatic endarteritic changes of the coronaries which in some cases may be related to the more typical forms of coronary disease (Weinstein, *loc cit*). It is obvious that we are dealing with a large field which is inadequately explored and which is filled with possibilities of diagnostic errors.

Pulmonary thrombosis, often complicated by pleurisy, may cause electrocardiographic changes which strongly resemble those of posterior infarction. The changes are thought to be due to reflex spasm of the pulmonary vascular bed which places sudden excessive strain on the right ventricle. Aggravation of the pain on respiration is a valuable but not conclusive symptom favoring inflammation of the pleura. Acute pericarditis occurs typically in young persons who have previously been well, very often the pain is preceded by a cold. There then follows a sharp precordial pain, often aggravated on deep inspiration. If the condition begins as a mediastinitis there may be pain behind the sternum and on swallowing. There follows a rather severe febrile reaction with temperatures somewhat higher than are seen in uncomplicated myocardial infarction. Often the characteristic changes in the electrocardiogram and the development of pericardial effusion will establish the diagnosis. This picture may closely resemble that of myocardial infarction in young persons.

CASE III—A 52 year old insurance executive who had previously been well attended a heavy business luncheon on August 9, 1944 following which he was indisposed. In the afternoon he developed severe abdominal pain which was diagnosed appendicitis and an appendectomy was performed that evening. Convalescence was uneventful and on the 18th he was allowed out of bed. Having been up about twenty minutes he felt faint, developed a sense of constriction about the chest, and dyspnea. There was at no time cough. A heart attack was suspected and an electrocardiogram was taken, it showed certain abnormalities which were interpreted as indicating myocardial infarction and the patient was treated accordingly. During the next five days the pain returned and he had some fever. He continued to be short of breath, but had no cough.

On August 23 the patient was admitted to the hospital where he arrived after a 100-mile ambulance ride. He was very sick with extreme dyspnea and vomiting. He subsequently quieted down and felt well except for dyspnea. On the 24th he had a pain across the right chest and soon another one in the left chest where a friction rub was heard. The electrocardiogram taken in the hospital similar to the one taken before, showed pathologic changes but not which were considered characteristic of infarction. An x-ray examination showed a definite enlargement of heart and shadows through both lung fields, suggestive of pulmonary infarction. The diagnosis was postoperative pulmonary infarction. For the next week he was comfortable, free from pain and fever and on September 3 he was returned home for further care. On September 4 he suddenly became worse with dyspnea and precordial pain and he died that afternoon. Autopsy showed a recent massive thrombus of the left pulmonary artery, several pulmonary infarcts, but no myocardial infarction.

PAIN ARISING FROM STRETCHING OF TISSUES

The stretching of various tissues in the body, even to the point of rupture, may be associated with a severe pain which may be ascribed to heart disease. This mechanism operates in a variety of disorders. Most dramatic is rupture of the aorta, sometimes with the formation of a dissecting aneurysm.¹⁶ The clue to the correct diagnosis lies in the proper evaluation of the history and symptoms. The stretching at

tearing associated with the occurrence of pneumothorax,¹⁷ have been mistaken for myocardial infarction. Abdominal organs, especially the stomach, may give rise to symptoms in a similar manner. Stretching of muscle must be the explanation of the pain arising from diaphragmatic hernia¹⁸ or even from the acute distention resulting from dietary indiscretion.

CASE IV—This 49 year old merchant was invited to a spaghetti feast on June 10 1944. In anticipation of the meal, he ate very little during the day but about 8 o'clock he sat down to a large and rich repast. In the course of the meal he had five good-sized hughballs. On getting home about midnight he felt nauseated, but managed to get to sleep. He awoke at 2 30 and felt thirsty. He drank two glasses of ice water and went back to sleep. At 7 30 he awoke with a 'terrific' pain across the epigastrium. baking soda and an enema increased the pain. He induced vomiting but the pain persisted. A hypodermic injection of morphine failed to relieve the pain. additional medications put him into a stupor which deepened into sleep from which he awoke the next morning when the pain was gone. A local consultant, a man of excellent judgment, and the family doctor were uncertain of the diagnosis. Electrocardiograms taken on June 14 and about July 20 and on August 22 were all alike and within normal limits. There was some widening (near 0.10 sec.) of the QRS complex, with a very shallow Q₁ and slurring of the downstroke of R. S-T segments and T waves were definitely normal in all leads.

As a matter of precaution, but not of conviction, he was treated as having had a myocardial infarction, although he had no more symptoms of any kind, neither cardiac nor digestive.

A physical examination on August 22, 1944 showed the heart to be transverse in position, but not enlarged. The action was regular with a rate of 90. There were no murmurs and the blood pressure was 112/70. The physical examination of abdomen was normal.

Though the possibility that he had had an infarction cannot be excluded there was no suggestive evidence other than the pain, for which, however another satisfactory explanation was available.

In such cases the differential diagnosis can be exceedingly difficult, it may in the last analysis be impossible to exclude one or other condition with certainty. Although the diagnosis of *acute indigestion* has lost favor, having so often led to the serious mistake of overlooking myocardial infarction, it still remains as a clinical entity which may closely resemble myocardial infarction.

The stretching of tissue may involve the heart itself, without infarction taking place, though the resulting pain may be immediately caused by ischemia. It has been suggested that such stretching occurs in the right ventricle in right ventricular strain and it is possible that some form of injury to the myocardium may result from acute heart strain and also from traumatic injury to the chest wall. This latter condition has medicolegal aspects which have been extensively discussed in the literature.

CASE V—A 22 year old factory worker was splitting cables to test their strength. Generally this was well within her capacity but on November 27 1943 one cable demanded an unusually hard pull and when it came apart she felt a

pain which extended from the second left intercostal space close to the sternum to the apex area. In the afternoon she developed breathlessness and the pain returned without effort on her part. This condition persisted to a varying degree during the next few days. Medical examinations at the time failed to reveal subjective findings and she gradually recovered as long as she did not exert herself.

However, on effort and under emotional strain she would develop a feeling as if her heart "drew up," she would get short of breath, her heart would beat fast and she would develop a "nervous chill." She would get such attacks at irregular intervals. They prevented her from holding a job up to the time of the examination (September 18, 1944).

There is now a compensation suit involved in the case.

The physical examination was entirely normal. The heart was well within normal limits as to size and shape. The heart rate was 84 and the rhythm regular. Over the pulmonic area was a soft systolic murmur and the electrocardiogram was entirely normal.

Realizing that this patient's symptoms may possibly have been aggravated by the consideration of compensation, this case must nevertheless be considered one of *effort syndrome*.

CASE VI—For five years this 42 year old doctor's wife had had attacks of viselike precordial pain radiating along the inner surface of the left arm.

The pain would come on once or twice a month, especially near her menstrual periods, at any time during the day or night, it could be caused by fright, scare or worry. Sometimes it was relieved by nitroglycerin, sometimes codeine was required for its relief. She was allergic to many things and had suffered migraine headaches.

She had been to several heart specialists and clinics without other satisfaction than a negative cardiac diagnosis which left her with her pain.

The physical examination on February 22, 1938 revealed a heart normal on fluoroscopic examination, a blood pressure of 142/84, pulse of 80 and no murmurs. The electrocardiogram was normal.

While she was in another room being prepared for fluoroscopic examination her husband told the physician that the first time she felt the pain was once when they returned from a party to find their home in flames with the children asleep on the second floor. Her reaction to this experience had been a severe precordial pain, which she henceforth felt whenever she became excited.

She was then treated by psychotherapy.

On March 3, 1939 her husband wrote "I am pleased to report that she is feeling fine just so long as she does not overexert herself and avoids worry."

THE THRESHOLD TO PAIN

In the evaluation of all of the conditions discussed in this paper the matter of the threshold to pain is important. It determines the severity with which the patient complains and it varies greatly from person to person, being influenced by the general state of the patient. It is lowered by previous pain and fatigue, raised by vigor and good health. Any given nerve path can be trained to become more sensitive if the patient focuses his attention on it, consequently, patients who watch for evidence of heart disease are more likely to feel it, irrespective of whether the impulses traveling along the nerve paths are physiological

or part of organic heart disease. When complaints of precordial pain as a simple result of fatigue and introspection occur in hyposthenic or nervous persons in whom a physical examination reveals normal cardiovascular findings, the diagnosis of neurocirculatory asthenia is easy, but when such complaints occur in persons who must be suspected of or are known to have organic heart disease, it may be extremely difficult to determine how much of the patient's complaint can be treated lightly. In the following two cases it is not clear how great a part was played by the hypersensitiveness of the patient's nervous system.

CASE VII.—This 47 year old lawyer of French descent was high strung and emotional. His brother whom he frequently saw was suffering from frequent and severe attacks of angina pectoris.

He consulted a physician because one year ago he had suffered occasional precordial pains. The pains across the chest were just severe enough to cause him to rest and would leave in two to three minutes. There were also sharp pains about the left clavicle. These symptoms disappeared but returned at the beginning of the year and have persisted since. They sometimes were brought on by walking but emotional strain did not seem to affect them.

The patient was of sedentary habits and smoked thirty to forty cigarettes a day.

The physical examination on May 19, 1944 was entirely normal. His blood pressure was 108/84. His heart shadow was well within normal limits and his electrocardiogram was entirely normal.

Thus there was nothing on which to base a diagnosis other than a rather typical history. The conclusion was that this patient's complaints were probably psychogenic but that a final diagnosis should be deferred.

CASE VIII.—A 40 year old insurance man, who weighed 215 pounds, was highly strung and overindulged in both food and alcohol. He had for two years complained of an ache in his left pectoral muscle. This ache was never severe, it came and went periodically more so after overindulgence and heavy smoking. Over the last two years the pain had not changed appreciably and it was not affected by physical strain or emotion.

Two weeks ago his business partner suddenly dropped dead with heart disease and this caused him to look into his own condition.

When seen on August 16, 1944, he appeared a large, pot-bellied looking man. The heart was definitely of normal size and outline under the fluoroscope. The action was regular with a rate of 88. No murmurs were heard. The blood pressure was 118/96. The electrocardiogram was normal (transverse heart).

The man was highly sensitive and all findings were near or within normal limits. Yet he had a slight increase in diastolic pressure and he presented the general appearance which one frequently sees associated with coronary disease at a somewhat later age.

The diagnosis was early diastolic hypertension and cardiovascular hypersthenia, but close observation for further developments was recommended.

Even trivial complaints should always be taken seriously in patients who are known to have coronary disease (especially if they have previously had an infarction) and who have been fairly free of symptoms in the recent past. These symptoms may be the harbingers of a violent eruption as is shown by Case IX.

CASE IX—This 50 year old artist had a very severe posterior infarction eighteen months before his death. Following his recovery he was in reasonably good health though he passed through periods of threatening left ventricular failure. At no time prior to his death was there evidence of any other infarction. When seen in June he had few symptoms and during the next three months felt exceptionally well. He resumed his work of etching and was very productive in his studio which was on the second floor. On September 17 and 18 he did not feel quite so well and complained of little sticking pains around his chest. On the morning of the 19th he woke at 7:00 A.M., early for him, with indefinite complaints of dyspnea and restlessness. When seen at about 3:00 P.M. he had no particular complaints, but he did not feel inclined to climb his stairs until he had been reassured.

The physical examination was entirely normal and there were no changes in the electrocardiogram since June 30 except slight T wave changes in the chest leads, which were ignored as such changes are frequently seen in patients with coronary disease. He was discussing his future plans including travel to Paris after the war. At 3:30 P.M. he left the physician's office with his usual brisk walk. About five o'clock his physician received an urgent call to his home and arrived a few minutes later to find him moribund, yet mentally clear, stating that he was dying. He died a few minutes later.

CONCLUSION

The purpose of this presentation has been to emphasize the multiplicity of conditions which give rise to pain over the precordium which can be mistaken for heart disease. Not until the history is complete and the objective evidence has substantiated the diagnosis can it be considered certain. The clinician must always approach the patient with the thought in mind that precordial pain need not mean coronary disease. Especially in young persons should coronary disease and myocardial infarction not be diagnosed on insufficient evidence. Since coronary disease has serious prognostic implications and should cause for important modifications of the patient's life, while other causes may be comparatively trivial and unimportant.

THE CLINICAL USE OF DIGITALIS PREPARATIONS

J K LEWIS, MD *

THE fundamental principles governing the proper use of digitalis are the same today as they were when first laid down by Eggleston¹ almost thirty years ago. New preparations, usually pure glucosides derived from various sources, have become available. These are effective preparations and have a definite place in therapy but in the majority of patients the drug of choice is the crude drug. Regardless of the preparation used, however, a knowledge of the general principles of digitalis therapy derived from studies on the crude drug and an appreciation of its virtues are essential if one is to obtain its full benefit.

ACTION OF DIGITALIS

A detailed account of the pharmacologic action of digitalis is beyond the scope of this discussion and may be found in the general references listed in the bibliography and in a recent paper by Gold and Cattell.² One should recognize that the action of digitalis on the heart is of two kinds, the first an effect on the rhythm of the heart which is brought about by vagal effects and by direct action on the conduction tissues of the heart, the second a direct effect on the heart muscle. The first effect is responsible for both the favorable and unfavorable effects on cardiac rhythm, the second for the over-all increase in the efficiency of the heart as a pump. Because of these different actions digitalis is useful in both arrhythmias and in failure, and when the two are combined.

USE OF DIGITALIS IN HEART FAILURE

General Indications—With few exceptions digitalis may have a beneficial effect on heart failure. It is effective in failure with peripheral edema and venous congestion as well as in failure manifested mainly by attacks of pulmonary edema. It is most effective in failure associated with auricular fibrillation and a rapid ventricular rate. It is also effective when there is sinus rhythm^{3, 4, 5, 6} and, although the chances of success are not as good as in the case of auricular fibrillation, spectacular responses are sometimes obtained. With sinus rhythm its effectiveness may be related to the nature of the underlying heart lesion but evidence on this point is not strong enough to bar its use with any of the ordinary varieties of cardiac lesions. Marvin⁴ found it most effective in arteriosclerotic heart disease while Wood⁶ found it most

From the Department of Medicine, Stanford University School of Medicine, San Francisco, California

* Associate Professor of Medicine, Stanford University School of Medicine

effective in rheumatic heart disease. It is probably ineffective in most instances of acute myocarditis but beneficial effects have been observed in the treatment of heart failure associated with acute rheumatic myocarditis. Its chances of success are poor in heart failure associated with constrictive pericarditis when there is sinus rhythm and it should not be used in treating the typical form of beriberi heart.

Indications Under Special Circumstances—There are special circumstances such as auriculoventricular block, coronary artery disease with angina pectoris or myocardial infarction and cardiac complications occurring with hyperthyroidism, acute infections or surgical procedures in which there may be some doubt about the advisability of using digitalis. Here again the presence of heart failure is the determining factor, but these situations deserve further comment.

Heart failure associated with all degrees of *auriculoventricular block* has been successfully treated with digitalis.^{7 8 9} Apprehension over its use in these situations arises from fear that digitalis through its effects on conduction will increase the degree of block or precipitate Stokes-Adams attacks. Precipitation of Stokes-Adams attacks would contraindicate its use, but it is doubtful if slowing of the rate through increase in the degree of block would have an unfavorable effect. In complete block the drug is usually considered to be safe since no further change in conduction can take place. However, in three patients with failure and complete block Schwartz⁸ reported fainting attacks in two and spells of unconsciousness in one during treatment with digitalis. All were deliberately given more than the usual dose of digitalis but this report suggests that it is not entirely free of danger under these circumstances. In partial block one might anticipate trouble since Stokes-Adams attacks may occur with an increase in the degree of block, a change which would be favored by digitalis. However, Blumgart and Altschule⁹ systematically digitalized a group of patients with partial block and did not observe untoward effects. In sixteen of the nineteen patients in their series the degree of block was limited to a delay in conduction. Campbell¹⁰ in observing block due to digitalis in a large series of patients noted no unfavorable effects. In this clinic one patient reported syncopal attacks during the course of 2:1 block induced by digitalis, and in a few ambulatory patients with complete block and mild failure spells of faintness and of palpitation have been reported by the patient during the administration of the drug. It seems likely therefore that digitalis may occasionally induce unfavorable effects in patients with various degrees of block, but when the chance of producing undesired effects is weighed against the possibility of relieving heart failure the decision must be to use it. It should be given with caution. A week or longer should be taken to digitalize the patient and he should be observed with more than ordinary care.

The indications for digitalis in heart failure in patients with *angina pectoris* or in those who have had myocardial infarctions in the past

are no different than with other heart lesions associated with failure. But with acute myocardial infarction the situation is different since both the drug and the disease favor precipitation of ventricular tachycardia and ventricular fibrillation. With mild degree of failure it is usually best to withhold digitalis since failure often disappears as the general condition of the patient improves. But with progressive failure or severe failure which is in itself endangering the patient's life, digitalis should be used. There is a definite risk connected with its use but it is not prohibitive and should be accepted just as one accepts the risk of using large doses of quinidine for ventricular tachycardia under the same circumstances. On theoretical grounds a ration of quinidine given along with digitalis should lessen the hazard of precipitating ventricular tachycardia, but I know of no data bearing on this point.

In heart failure with *hyperthyroidism* digitalis is indicated just as it is in heart failure associated with other types of lesions. In some patients with auricular fibrillation more than the average amount of digitalis is required to slow the ventricular rate, but as a rule the dose is within the expected range. It is of no use in slowing the rapid sinus rhythm of uncomplicated hyperthyroidism.

Discussions of the indications for the use of digitalis in heart failure complicating infections and surgical procedures are included mainly to emphasize the fact that shock and shocklike states which complicate these conditions are not heart failure and are not benefited by digitalis. However, these conditions are at times complicated by heart failure especially in older individuals and in those who have a chronic heart lesion. Under these circumstances digitalis should be used in the usual manner.

Christian¹¹ has advocated the use of digitalis in certain patients who may later develop heart failure for the purpose of preventing it. Although this proposal has merit there is little experimental or clinical evidence to support it, and the decision to use it for this purpose depends largely on the personal opinion of the physician.

The Administration of Digitalis in Heart Failure—One now has the choice of a wide variety of effective digitalis preparations. The newer preparations, usually pure glucosides from various sources, have a definite place in digitalis therapy but in most cases pills, compressed tablets or capsules made from the leaf should be used. These preparations retain their potency over long periods of time unless they become moist, and the size of the individual dose is uniform. The tincture may be unpleasant to take and deteriorates to some extent with age, but its main disadvantage is the difficulty in obtaining uniform dosage because of the variation in the size of drops. One rarely encounters difficulties due to variation in the strength of the drug and even if this should occur it can be recognized by the effects on the patient.

The purpose of digitalis therapy is to produce the optimum therapeutic effect within a short space of time and to maintain this effect

The requirements are seldom outside the range of 0.1 to 0.2 gm per day, although there are many patients at either extreme. All gradations of dosage can be conveniently obtained with 0.1 and 0.2 gm tablets. When the requirements are not met by a regular daily dose of 0.1 or 0.2 gm, a satisfactory ration may be obtained by giving a tablet every other day or five or six times weekly. Only a few patients require more than 0.2 gm daily, and marked sensitivity is rare.

It is usually simple to judge, with both the initial and maintenance doses, when the optimum therapeutic effects have been obtained. When there is auricular fibrillation the heart rate, not the pulse rate, is a simple and accurate guide. A resting heart rate of seventy to eighty beats per minute is desirable. With sinus rhythm one is guided by careful observation of the signs and symptoms of heart failure. If improvement is striking, with relief of dyspnea and orthopnea and disappearance of signs of congestion, the problem is simple. If improvement is less obvious it may be necessary to push the drug to the point of producing mild toxic effects, since there is often only a narrow margin between the effective therapeutic and toxic doses.

Toxic Effects—Of the toxic symptoms loss of appetite, nausea of a particularly disagreeable sort and vomiting are the most common. Diarrhea is less common and yellow vision is rare. Disturbances of rhythm make up the remaining toxic effects. Ventricular premature beats giving rise to bigeminal rhythm or occurring irregularly are common, but those present before digitalis is used often disappear afterward and do not contraindicate its use. Ventricular tachycardia, auricular tachycardia, often with auriculoventricular block, auricular fibrillation and flutter and auriculoventricular nodal rhythm sometimes occur. Various degrees of auriculoventricular block are not uncommon but sino-auricular block is rare. The most frequent arrhythmias, and in many cases the less common ones, can be recognized at the bedside. However, ventricular tachycardia, the most serious of all the toxic effects, may be difficult to recognize. It occurs almost exclusively with either gross overdosage or with the most severe degrees of cardiac damage. It may be suggested at once by a sudden increase in heart rate, but this effect is often obscured since many of these patients already have a rapid rate. It should be suspected, then, not only when there is a sudden increase in heart rate but when there is a gradual increase in rate or failure of the expected slowing of the heart after an adequate dose of digitalis. An electrocardiogram will reveal at once the curious alternating ventricular complexes characteristic of ventricular tachycardia due to digitalis. This plan will also insure the recognition of other arrhythmias due to toxic effects of the drug.

Except in the case of moderate lengthening of conduction, digitalis should be stopped when any of the toxic effects appear, but it need not be abandoned. It should be withheld until they are gone, then resumed in a smaller dose. When toxic effects occur with small amounts of the

drug, other preparations should be tried. Their use will be discussed later.

Contraindications—If the indications for the use of digitalis as outlined above and the rules regarding toxic effects have been observed, there is little more to say regarding contraindications. Digitalis is contraindicated in ventricular tachycardia and in the typical form of beriberi heart. It is said to be contraindicated in hypersensitive carotid sinus syndrome, but in this clinic it has been used in the treatment of heart failure in a number of such patients without inducing unfavorable effects. It is likely, however, that in some patients with this syndrome digitalis may aggravate the symptoms because of its effects on the vagus. It should, therefore, be used with caution.

Duration of Treatment—There is no general rule to guide one in determining how long digitalis should be given but in general, once it has been found to be effective in the treatment of heart failure, it should not be discontinued. It may be withdrawn in patients in whom the cause of the heart failure can be removed, such as those with Graves' disease or arteriovenous fistula. At times it may be withdrawn in patients in whom heart failure is precipitated by some factor which is not likely to be repeated, such as an acute infection or a temporary arrhythmia.

Use of Pure Glucosides Having a Digitalis Action.—In Europe various glucosides having a digitalis action have been widely used but in the United States interest in their use is comparatively recent. The ones most commonly used are *cedilanid* and *digoxin* obtained from *Digitalis lanata*, *urginin* obtained from squill and *strophanthin*. All are effective preparations and have a definite place in cardiac therapy. They have some advantage over powdered leaf since they are pure substances and the dose is determined by weight rather than by biological standardization, but if one considers the uniform strength of present day preparations of powdered leaf and the fact that the dose of any preparation must be determined by the effects on the individual patient, these advantages become largely theoretical. There may be other advantages. Moe and Visscher¹² showed in animals that *cedilanid* was less toxic in the sense that there was a wide margin between the effective therapeutic and toxic doses. Occasionally this effect appears to be demonstrated in man. Certain individuals who cannot be digitalized with powdered leaf because of the early appearance of toxic effects may at times be successfully treated with one of the pure glucosides. Many times the same toxic effects will appear but one succeeds often enough to warrant the systematic trial of pure glucosides in such patients.

Parenteral Administration of Digitalis Glucosides.—Digitalis glucosides are also useful when parenteral administration is indicated. Although the use of *strophanthin* for this purpose has been known for many years, it has never been widely used in this country perhaps because it was seldom available or was available only in a preparation of uncer-

tain strength. However, reliable preparations of cedilanid, digoxin, strophanthin and ouabain are now readily available and are to be preferred when intravenous administration is indicated.

Parenteral digitalis administration is indicated only in emergencies, in patients who cannot take the drug by mouth, and at times in arrhythmias.

In emergencies reference has always been made to the rapid effects of venesection and oxygen administration, but often facilities for instituting these measures are not immediately available. The administration of any of the pure glucosides is simple and they are rapidly effective, maximum effects occurring within from five minutes to two hours.

ORAL AND INTRAVENOUS DOSAGE OF COMMONLY USED CARDIAC GLUCOSIDES

Preparation	Digitalizing Dose		Daily Maintenance Dose (Oral)	Reference
	Oral	Intravenous		
Cedilanid	6.25 mg in 48 hrs 7.5 mg in 72 hrs	1.6 mg 1.2 mg followed by 0.4 mg every 3-4 hrs until digitalized	0.75-1.25 mg 0.5-2.5 mg, average 1.6 mg	Fahr and La Due ¹⁸ Sokolow and Chamberlain ¹⁹
Digoxin	1.0-1.5 mg	0.75-1.0 mg	0.5 mg	Wayne ¹⁵
G-Strophanthin (Ouabain)	0.5 mg			Batterman, Rose and DeGraff ¹⁶
Urginin	6.5-14.0 mg in 72 hrs Average 9.0 mg		0.5-1.5 mg, average 0.95 mg	Chamberlain and Levy ¹⁷

When the drug cannot be taken by mouth one has the choice of rectal administration of tincture or suppositories, and intravenous, intramuscular or subcutaneous administration of one of the pure glucosides. Digoxin is irritating and must be given by vein. Any of these methods is effective but the assurance that all of the drug will be available makes the intravenous route preferable. It may be poorly absorbed from muscle and subcutaneous tissues in edematous individuals and it is sometimes expelled when given by rectum. The pure glucosides, either with oral or intravenous use, are administered according to the same principles which govern the use of the crude drug and the same toxic effects may occur. Before any intravenous preparation is given one must be sure that the patient has not recently received digitalis or any preparation having digitalis effect.

The dosage for oral and intravenous use of the preparations is given in the table. In emergencies the full dose should be given at once but in other situations some physicians prefer to divide the initial therapeutic dose into two equal portions given at an interval of several hours.

USE OF DIGITALIS IN TREATING CARDIAC ARRHYTHMIAS

Digitalis has a definite place in the treatment of cardiac arrhythmias both for the purpose of preventing them and for terminating them. Its use in this field deserves more consideration than it has received in the past, and takes on added importance because of the dwindling supply of quinidine.

Prevention of Paroxysmal Auricular Tachycardia—The use of digitalis for the purpose of preventing attacks of paroxysmal auricular tachycardia is mentioned in some texts but only Levine¹⁸ feels that it is superior to quinidine, and there is little information in the literature¹⁹ suggesting its use. Paroxysmal auricular tachycardia is a common disorder but its course is so unpredictable that it is difficult to collect a group of records suitable for critical analysis of the effectiveness of digitalis or for comparing its effectiveness with that of quinidine. In this clinic when preventive treatment is indicated we prefer to try digitalis first, partly because we have the impression that it is at least as effective as quinidine and also because it has certain practical advantages over quinidine, particularly for a form of therapy which must often be indefinitely continued. Digitalis is cheaper, only one daily dose is required as compared with a minimum of three with quinidine, and if the daily dose is accidentally omitted there will be no appreciable reduction in the effective amount of digitalis while the effects of quinidine rapidly diminish. It is not always effective and one must remember that digitalis is contraindicated in ventricular tachycardia. If this is suspected digitalis should not be given unless there is electrocardiographic proof of the nature of arrhythmia.

The following brief case reports illustrate its effectiveness.

CASE I.—Mrs. D. P., aged 34 entered complaining of attacks of palpitation for four years occurring regularly before each menstrual period and accompanied by nausea, vomiting and emotional upsets. They occurred despite quinidine. Physical examination, x ray of the heart, electrocardiograms and basal metabolic rate showed nothing remarkable. No attacks were observed during a week's observation but the day after dismissal she returned because of an attack of twelve hours duration. The heart was regular at 200 beats per minute. There were no signs of heart failure and the attack was stopped after 2.2 gm of quinidine in twenty hours. Electrocardiograms during the paroxysm showed a regular rhythm with a rate of 200, no P waves, a QRS of 0.11 seconds and deeply inverted T waves in Leads II and III.

The patient was dismissed to take quinidine 0.2 gm three times daily but returned in one month because of a similar attack of three days' duration. The heart rate was again 200 and the electrocardiogram the same except for readily identifiable P waves preceding each ventricular complex. The paroxysm ended after 1.2 gm of quinidine in nine hours. She was digitalized and dismissed on a

maintenance dose of 0.1 gm of powdered leaf daily. No attacks occurred in the next three months.

CASE II—Mr F G., aged 65, came to the clinic because of attacks of palpitation accompanied by dizziness for three months. General physical examination and x-ray examination of the heart were not remarkable. Electrocardiogram showed the short PR, wide QRS syndrome. Further records on numerous occasions showed paroxysms of auricular tachycardia. These frequently consisted of short paroxysms which came on with inspiration and stopped during expiration. They could be completely abolished by tilting the patient to an angle of 65 degrees and made to reappear by tilting back to the horizontal position. On 45 drops of tincture of belladonna daily they appeared to become less frequent but were not abolished, but with a maintenance dose of digitalis of 0.2 gm daily they completely disappeared and could not be induced, on many tests over a period of three months, by deep inspiration or tilting back and forth between the vertical and horizontal.

CASE III—Miss D M., aged 50, was seen because of attacks of tachycardia occurring several times a week for the past few months. Physical examination showed nothing remarkable. An attack of tachycardia with a rapid regular rhythm of 180 was observed, which stopped with carotid sinus pressure. On a maintenance dose of 0.1 gm. of digitalis daily only a few attacks occurred in the next few months. These were brief and caused little inconvenience.

Prevention of Paroxysmal Auricular Flutter and Fibrillation—Digitalis is also useful as a preventive measure in the treatment of paroxysmal auricular flutter and fibrillation. Its use for this purpose has been objected to on the grounds that it might transform a paroxysmal arrhythmia into a permanent one, since digitalis sometimes induces arrhythmias. However, this is so uncommon that it does not constitute a serious contraindication. In some cases²⁰ digitalis clearly prevents attacks, in others it is beneficial even though paroxysms occur since the increase in ventricular rate with the paroxysm is modified or prevented by digitalis. Patients treated in this manner have reported little inconvenience from attacks when they have occurred, and on a few occasions attacks of paroxysmal auricular fibrillation have been observed in individuals at a time when, because of a slow ventricular rate, they were not aware of any change in heart rhythm. Gold²¹ has stated that this does not occur, at least in individuals without heart failure, but we have not seen patients of this sort.

When digitalis is given for the purpose of preventing paroxysmal arrhythmias, it is best to give it by the method suggested previously for slow digitalization.

Termination of Chronic Auricular Flutter—Fahr and LaDue¹³ have reported reversion to normal rhythm in a number of patients with chronic auricular fibrillation following intravenous cedilanid. One does not as a rule expect this to take place but digitalis is effective for this purpose in auricular flutter and in paroxysmal auricular tachycardia. Its action in auricular flutter is well known. The usual instructions are to digitalize the patient, often to the point of producing mild toxic symptoms, with the expectation that auricular flutter will be converted to auricular fibrillation. If this occurs, digitalis is withdrawn and,

if the treatment is successful, reversion to normal rhythm then takes place. Withdrawal of digitalis when auricular fibrillation occurs complicates the treatment since it is often difficult to distinguish between the two arrhythmias without frequent electrocardiograms, particularly after digitalis has been given. This step seems illogical and experience in this clinic has shown it to be unnecessary. The change from auricular fibrillation to sinus rhythm often occurs in too short an interval to have allowed time for a significant reduction of the amount of digitalis in the body. It may be necessary at times to reduce the dose of digitalis with the appearance of auricular fibrillation, since this may be accompanied by a considerable fall in ventricular rate. Otherwise the management of auricular flutter is the same as it is for auricular fibrillation. Enough digitalis is given to lower and maintain the ventricular rate at 70 to 80 beats per minute, and one is not obliged to determine from day to day whether or not auricular fibrillation has appeared. If this treatment fails to restore normal rhythm, the usual plan of giving quinidine is followed.

In this clinic twenty-four patients with chronic auricular flutter have been treated according to this plan. With digitalis alone, normal rhythm was restored in fourteen, or 57 per cent. Of the remaining patients, those in whom digitalis had failed, normal rhythm was restored with quinidine in four, two were left with chronic auricular fibrillation and four with chronic auricular flutter.

Anything which would shorten the treatment of auricular flutter would be welcome, since reversion to normal rhythm is seldom accomplished in less than a week. It is therefore of considerable interest that there are now on record a number of instances in which intravenous glucosides have brought about a rapid reversion to normal rhythm. Parkinson and Bedford²² observed it in two patients after intravenous strophanthin. Using cedilanid by vein, Fahr and LaDue¹³ reported reversion to normal rhythm in two patients within a few minutes and in a third patient within twenty-four hours. Sokolow and Chamberlain,¹⁴ using the same preparation, noted reversion to normal rhythm in three patients within eighteen, thirty-six and forty-eight hours. Fahr and LaDue administered the full therapeutic dose at once while Sokolow and Chamberlain used a less rapid plan of administration. These reports should encourage further trial of intravenous glucosides for this condition with the hope that in at least some patients with auricular flutter the period of treatment can be shortened.

Termination of Paroxysmal Auricular Tachycardia—There is seldom urgent need of terminating attacks of paroxysmal auricular tachycardia since the attacks are usually self-limited. However, in prolonged attacks or attacks with an extremely rapid ventricular rate, serious heart failure may occur even with a normal heart. Quinidine is probably the drug of choice in this state but it is important to know that intravenous digitalis preparations may also be effective. Wilson and Wishart²³ first reported the successful use of intravenous digitalis for this

purpose, and Fahr and LaDue¹³ report five cases successfully treated with intravenous cedilanid. Curiously enough, the largest body of evidence bearing on the effectiveness of digitalis in paroxysmal auricular tachycardia is contained in a report by Hubbard²⁴ concerning this condition in infants. Nine infants, five of them three weeks old or less, were successfully treated by intramuscular digifolin. The initial dose was 0.1 gm and the total amount given any patient was 0.3 gm. In some patients the total amount was given in three doses within twenty-four hours.

While there is not enough information to permit an adequate definition of the place of digitalis in the treatment of paroxysmal auricular tachycardia for the purpose of terminating the attack, it should be considered after quinidine has failed. It has an advantage over other preparations in patients with heart failure because of the general effect of digitalis on heart failure and because significant slowing may occur²³ even if the arrhythmia persists. It should not be given without electrocardiographic proof of the nature of the tachycardia.

CLINICAL RELATIONSHIPS BETWEEN ARTERIAL HYPERTENSION AND THE KIDNEYS

DAVID A. RYTAND, M.D.*

ARTERIAL hypertension is only a sign of disease, not necessarily a disease in itself. Even though careful search of most hypertensive patients usually fails to disclose a reason for the abnormal pressure, it is still useful in protecting other patients from improper treatment, in the management of the hypertensive patient, and in arriving at a prognosis. During this search, it is not uncommon to discover proteinuria or other evidence of renal disease, the purposes of this paper are to discuss the diagnostic and therapeutic problems raised by the occurrence of a renal lesion in the hypertensive patient, and to review the pertinent basic concepts which have been so well summarized recently^{1, 2, 3}

ETIOLOGIC RELATIONSHIPS BETWEEN HYPERTENSION AND THE KIDNEYS

At least logically, there are three ways by which hypertension and the kidneys could be related: renal lesions might cause arterial hypertension, hypertension might result in renal disease, and still other disorders might simultaneously damage the kidneys and elevate the blood pressure. Unfortunately, the following separation of certain situations into these three categories is more certain in black and white than it is in actual patients.

Renal Disease Causing Hypertension—Many varieties of bilateral primary disorders of the kidneys result in hypertension, especially when renal failure (uremia) is present; among others, these include glomerular nephritis in early and late stages, polycystic disease, pyelonephritis, and obstruction of the urinary tract. Patients with periarteritis nodosa, disseminated lupus or related syndromes are usually hypertensive only with associated renal failure: their arterial pressures are normal either when the kidneys are not involved or when renal tubular degeneration predominates.⁴ These syndromes therefore seem to behave as glomerular nephritis in relation to hypertensive effect.

The mechanism by which renal disease elevates arterial pressure is not established, nor has it been thoroughly studied. Diffuse renal lesions have been compared without adequate basis, to experiments in which the pressure is raised by partial occlusion of the renal artery, it has been claimed that renal ischemia is responsible for hypertension in both. Although the perfusibility of the kidneys removed at necropsy

* Assistant Professor of Medicine, Stanford University School of Medicine.

is very low when renal damage has caused death in uremia,⁵ indirect estimations of renal blood flow during life in patients with glomerular nephritis seem to indicate hyperemia.⁸ In rats made hypertensive with a diffuse renal lesion after subtotal nephrectomy, blood flows through the abnormal remnant of kidney at a normal rate.⁶

On the other hand, the rate of renal blood flow is surprisingly low in subjects with coarctation of the aorta,⁷ in whom the kidneys are apparently normal otherwise, it has been suggested that the arterial hypertension with this anomaly represents the clinical counterpart of the Goldblatt type of experiment. Experimental studies on this variety of hypertension, caused by partial occlusion of a renal artery, show that it persists after denervation by transplanting the kidney,⁸ thereby involving a humoral substance. Whether this constricts arterioles by peripheral action or via the central nervous system⁹ is not certain, and its relation to the renin-angiotonin series is not established.

Recent attempts have not yet succeeded in naming the juxtaglomerular apparatus as the precise source, within the kidney, of renal hypertension.³

In the last few years attention has been directed to unilateral renal lesions, usually atrophic pyelonephritis, as a cause of hypertension, since such lesions are removable they might be of more practical importance than bilateral ones. Unfortunately, arterial hypertension is rarely associated with lesions of this type and is even less often relieved by nephrectomy,^{1, 10} we have seen only two successful results in this clinic.

Complete removal of both kidneys causes little or no increase in arterial pressure experimentally. Clinically, hypertension is rare in acute anuria and is uncommon in some varieties of chronic renal disease, these include the "surgical" types of renal lesions, the nephrotic stage of glomerular nephritis, amyloidosis, and the lesions with multiple myeloma and subacute bacterial endocarditis (even with uremia). There is no satisfactory explanation for the usual failure of these lesions to elevate arterial pressure.

Essential Hypertension—High blood pressure follows gross renal disease in only a small proportion of all hypertensive patients, and is even more rarely associated with other etiologic factors such as a tumor of the adrenal medulla. In the great majority of cases, careful search fails to reveal a reason for the elevated diastolic pressure level, in these patients it may then be said that essential hypertension is present.

Now it is obvious that there must be some underlying reason for the generalized arteriolar constriction which is manifest clinically as hypertension, the renal factor was partially discussed above. It may now be added that essential hypertension is regarded by some to be of renal origin, although this view is becoming less popular as the evidence for it grows more complex.^{1, 2}

Although an obscure metabolic fault in the kidneys² may eventually

become established as the cause of essential hypertension, simple renal ischemia increasingly seems less likely to be involved. The arteriolar lesions found in the kidneys at necropsy are usually absent earlier in the disease,¹¹ and even after death renal perfusibility is not often decreased in the absence of uremia.⁵ Clinicians have long been impressed by the "nervous" element in patients with essential hypertension, studies have newly emphasized the fact that organic disease of the central nervous system in man and experimental interference with the nervous system in animals may be followed by an elevation of arterial pressure. A neurogenic element has been implicated even with renal hypertension.⁹

Hypertension Causing Renal Disease.—The concept that essential hypertension had its origin in renal ischemia arose, at least in part, from the fact that vascular changes are associated with hypertension of any cause, and are often prominent in the renal vessels.

These changes are of two kinds, corresponding roughly to the size of the involved vessels. First, renal arterioles presumably participate in the generalized systemic arteriolar constriction which causes hypertension, as well as in the medial hypertrophy which is an early sequel. Secondly, increased arterial pressure initiates or accelerates atherosclerosis, it is chiefly this alteration in the larger arteries which complicates the course of the hypertensive patient, as by occluding cerebral or coronary arteries.

Renal arterial pressure remains normal distal to the partially constricted artery responsible for hypertension in the rest of the experimental animal, under these conditions, vessels in the kidney are protected from the changes occurring elsewhere.¹² In essential hypertension there is no such protection and therefore renal arteriosclerosis accompanies cerebral, retinal and cardiac arteriosclerosis.

This event may add a renal factor to hypertension which arose elsewhere, and produces abnormal results when renal blood flow and other functions are measured by modern methods.¹⁻³ It is of more practical importance to recognize that renal arteriosclerosis, while not often causing death in uremia, is the lesion responsible for the abnormal urine of most hypertensive patients.

Anatomic changes in the shrinking kidneys are evident in the urine in the form of moderate amounts of protein, with a few casts, erythrocytes, leukocytes and renal tubular cells in the sediment. If heart failure supervenes, the urinary abnormalities increase in degree with renal congestion. Gross hematuria may accompany the malignant stage of essential hypertension with arteriolar medial necrosis, or may appear as part of uremia's purpura. As function decreases, urine becomes dilute and its specific gravity less variable. Rough tests of the blood show retention of metabolites.

Hypertension and Renal Lesions Associated with a Third Factor.—More than a few uncertainties were noted above, we know even less about

states in which the blood pressure and kidneys are involved more or less at the same time in the presence of a third process. One could, of course, include the periarteritis nodosa group and even acute glomerular nephritis in this section, but two other illustrations may be better.

The first of these is that of *intercapillary glomerulosclerosis*, a renal lesion usually found only in middle-aged patients with diabetes mellitus, and then especially together with a syndrome of arterial hypertension, marked proteinuria and abnormal urinary sediment, edema due chiefly to hypoproteinemia, and renal failure.¹³ The diabetes almost always comes first, and is mild. Microscopic lesions may be of severe degree without the complete syndrome, and the causal relationships are not yet clear. The syndrome is of particular interest because it is uncommon for hypertension to exist with edema caused by low concentration of the serum protein and with intense renal tubular degeneration and proteinuria (the nephrotic syndrome).

This unusual combination is even more striking in *eclampsia* (*pre-eclampsia*), no longer thought to be the result of disturbed renal function.¹⁴ Here again one finds a third factor, an abnormal state during pregnancy, associated in unknown ways with hypertension and a degenerative renal lesion, and with edema often a consequence of hypoproteinemia. Unlike the syndrome in the previous paragraph, renal failure is rare in *pre-eclampsia*. Prolonged toxemia is often followed by persistent hypertension.

Pre-eclampsia occurring late in pregnancy is to be distinguished from those situations in which the course of previously existing hypertension or renal disease is complicated by the occurrence of pregnancy. Under these conditions the original disorder may remain relatively unchanged, but usually becomes worse comparatively early. After termination of pregnancy, the underlying condition may be little or no more severe than before. *Pre-existing* hypertension is much more apt to cause trouble than a previous renal lesion with normal pressure and function.

GUIDES TO DIFFERENTIAL DIAGNOSIS

With the above material as background, the significance of family and personal histories, physical examination and laboratory studies may now be discussed.

Family History—The patient with essential hypertension may tell of a high incidence of hypertensive disease or its sequels in his family history. So may the one who has polycystic kidneys, although he is apt to speak of kidney trouble. "High blood pressure" as a cause of death in aged relatives may usually be ignored, as an elevation of systolic pressure with normal diastolic pressure is common with arteriosclerosis, the latter, not hypertension, may also have been responsible for cardiac and cerebral manifestations.

Personal History—The recent "present illness" part of the story is apt to consist of shortness of breath, fatigue or other complications

of hypertension, it must be carefully heard for its clues to proper management of the patient. More rarely the complicated illness suggests a syndrome in the periarteritis nodosa group as the patient tells of asthma, joint troubles and a rash, the aging gentleman's difficulty in emptying his obstructed bladder may be important, abdominal pain in another leads to the discovery of polycystic kidneys, the presence of advanced pregnancy scarcely needs telling.

The past personal history is more useful in evaluating the significance of renal disorders accompanying hypertension. In earlier examinations (for life insurance, pre-employment, military service, and so forth), was high blood pressure found before or after albumin in the urine? Had the patient had trouble, or the physician betrayed alarm toward the end of pregnancy? Was a bad sore throat followed shortly by the puffy eyelids or smoky urine of acute glomerular nephritis? Had there been a period of painful burning or frequent urination, or chills with fever and backache, as the early events of urinary tract infection which has become chronic pyelonephritis? Was there ever an operation on or about or below a kidney as a possible cause of unilateral renal disease? Was the urine ever bloody possibly at a time when there was severe colicky pain of a stone? Such specific questions help in deciding whether a renal lesion found with hypertension plays an etiologic role or is merely a complication.

Physical Examination—The physical examination also serves two purposes, first in evaluating the damage done by hypertensive disease and secondly in seeking a reason for hypertension. As to the latter, simple inspection reveals the typical facial erythema with disseminated lupus, polycystic kidneys are found on palpation, dilated intercostal arteries and delayed, small or absent femoral pulses indicate coarctation (with which hypertensive retinopathy is strangely uncommon). Since these are so rarely found, examination is most helpful in finding what harm has been done by elevated pressure in the way of vascular changes, particularly one notes any signs of cerebral arteriosclerosis, looks for retinal damage, and searches for the cardiac enlargement, gallop, basal rales or systemic congestion of heart failure. These, more than the mere level of arterial pressure, determine the prognosis and guide management of the patient.

Laboratory Studies—There are only three really important laboratory aids for an understanding of most patients with renal disease and hypertension: these are careful examination of the urine, a simple test of renal function, and pyelograms by intravenous injection of a contrast medium if renal function seems normal.

To be sure, other methods of study are indicated in a very few patients. It may be helpful to find an elevated concentration of serum globulin when one of the periarteritis group is suspected, or to confirm that suspicion by muscle biopsy, a roentgenogram may reveal the notched ribs and absent aortic knob typical of coarctation. Still

other laboratory studies may be useful in assessing what damage hypertensive disease has done. The radiologist's finding of cardiac enlargement and pulmonary congestion will often confirm the results of physical examination or the patient's story of breathlessness. The electrocardiogram is apt to be misleading, except for characteristic changes of myocardial infarction, because of the high incidence of abnormal T waves with left ventricular preponderance.

The *urine* may be apparently normal not only when renal disease is absent, but also in two situations in which renal lesions play a part in elevating arterial pressure. First, with complete obstruction of a ureter the abnormal side contributes *nothing* at all to the urine, secondly, healed or atrophic pyelonephritis may similarly alter blood pressure with little or no urinary evidence of its presence. One must also remember that hyaline casts and erythrocytes are dissolved in alkaline urine, particularly if dilute, and that it is more difficult to detect small amounts of protein in dilute urine. Concentration tests are best used not as tests of renal function but as a means of obtaining concentrated urine suitable for examination, this should include the method of Addis¹⁵

Erythrocytes and especially leukocytes in the sediment, with small degrees of proteinuria, suggest pyelonephritis. This is sometimes erroneously diagnosed when glomerular nephritis is present, an error caused by misinterpretation of the latter's renal tubule epithelial cells as "pus cells." Casts (hyaline, granular or epithelial) do not mean glomerular nephritis, but occur with any diffuse renal lesion. It is obvious that urinary tract infections are commonly found as complications of hypertension, they cause it much less often.

Early in glomerular nephritis the predominance of blood casts and erythrocytes over leukocytes and tubule cells simplifies the diagnosis. Later, blood casts may be found only after long search. In the nephrotic stage such evidence of glomerulitis is usually lacking, the urine is full of protein, hyaline casts with fat droplets, and renal tubule cells packed with fat (oval fat bodies), similar findings occur in other nephrotic syndromes. Later in glomerular nephritis, the renal lesion as judged by urinalyses seems less intense, there are moderate and roughly proportional excesses of protein, erythrocytes, leukocytes and renal epithelial cells, and granular or epithelial casts. With the dilute urine of advanced renal disease hyaline casts are rare, but broad casts appear, the latter are found with renal failure of many causes. Both the urine and clinical features of late glomerular nephritis are indistinguishable from those of renal arteriosclerosis following essential hypertension. The presence of blood casts, fatty cells or casts, and broad casts all at once is highly suggestive of one of the periarteritis nodosa syndromes.⁴

Tests of renal function need not be complicated. The main question is whether renal disease is confined to one kidney or has involved both, the latter is established by finding an elevation of the blood

urea¹⁶ or creatinine concentration above normal upper limits (generously 50 mg and 2 mg per 100 cc respectively) Some clinical laboratories seem able to measure blood urea-nitrogen (25 mg per 100 cc.) or total nonprotein nitrogen (50 mg per 100 cc.) more accurately than urea Creatinine is less subject than other substances with non-protein nitrogen to extrarenal sources of elevated concentration, urea, for example, may be increased in the blood in the absence of any renal disease. Otherwise, nothing is gained by measuring more than one of these substances, and very little useful information is added by determinations of dye excretion or clearances

Intravenous pyelography will rarely be either successful or helpful when simple tests show reduction of renal function, then measurement of residual urine volume in men and stereoscopic roentgenograms of the kidney region (for renal size or stones) are in order Intravenous pyelograms of the hypertensive patient are made either in the seeming absence of a renal lesion (normal urine) or in the presence of urinary abnormalities without reduced renal function, in an effort to uncover the rare instances of hypertension caused by renal disease amenable to specific treatment, this really means a unilateral abnormality

RENAL DISEASE AND THE TREATMENT OF HYPERTENSION

Enthusiasm aroused by apparent discovery of such a cause must be tempered before advising nephrectomy Minor deviations from perfectly normal pyelograms are common, and apart from the operative risk it is sometimes harmful to remove a kidney which appears to be functionless,¹⁰ even in apparently well selected patients unilateral nephrectomy seems to be successful in curing hypertension in only one case out of ten^{1 10}

Atrophic pyelonephritis, with a small and functionless kidney on intravenous pyelography, is the lesion most frequently found when good results follow nephrectomy Precise indications for the latter are not yet established. Of two successful cases in this clinic,¹⁷ repeated pyelography in one showed unilateral loss of function but the removed kidney appeared almost normal, in the other, a previous renal operation had led to diffuse lesions in a kidney which nevertheless was able to concentrate the contrast medium

Having found a suspicious appearance, intravenous pyelography should be repeated If the lesion is still present, cystoscopy is necessary, not only for further exploration of the abnormal side but to obtain urine from, and assure the normal function of, the other side. Complete normality of the opposite kidney will not guarantee success on nephrectomy but abnormalities there cast grave doubt on the advisability of operation

The *pre-eclamptic toxæmia of pregnancy*, when mild, may be controlled by management which stresses rest and sedatives, with a diet

providing an adequate amount of protein while restricting sodium, diuretics are sometimes necessary. Unfortunately, prolonged toxemia is frequently followed by a form of hypertension which apparently is not distinguishable from essential hypertension, this does not so often come after severe toxemia, which is not allowed to be present very long. Since fetal mortality in toxemia is lower when labor is induced a month before term, such interference seems best for both mother and child when toxemia persists in spite of modern management.

But for the removal of a fetus from the pregnant uterus or the rare attack on a unilateral renal lesion, the conditions reviewed above are not often subject to specific therapy. Yet the presence of kidney disease alters treatment of the hypertensive patient in various ways.

Sulfonamides will frequently be given to patients with *urinary tract infections*, with impaired renal function more than the usual precautions should be taken. We are not convinced of their reported beneficial action in glomerular nephritis, but the latter does not contraindicate their use when necessary. Those who use thiocyanate in hypertension should avoid it when renal lesions are present.

The management of *congestive heart failure* in hypertension is made more difficult by the presence of true uremia (not including the relatively slight reduction of function in the congested kidney). Mercurial and even other diuretics may then not be used safely, digitalis and related glucosides more likely produce vomiting, and the associated anemia necessitates more thought before phlebotomy. One often desires to replenish the sodium and water stores of the uremic patient who is dehydrated, this must be done cautiously in the presence of hypertension, even when heart failure is not obvious, in order to avoid pulmonary edema.

While dietary reduction of urinary nitrogen excretion is not useful in hypertension without renal involvement, there is every reason to believe it reduces renal work and is therefore indicated when bilateral kidney damage is present¹⁸ in an effort to minimize progression of the lesion. Urinary nitrogen is best reduced by a diet which first supplies an adequate number of calories and which daily gives about 0.5 gm of protein per kilogram of body weight, to the latter must be added an amount of protein equal to its daily loss in the urine. Dietetic details, including the need of vitamin and mineral supplements, must be decided in each individual case.

Finally, when section of the splanchnic nerves is contemplated, the presence of a renal lesion requires further consideration. The chances of a successful result are worst in those hypertensive patients who most need help, those with renal damage in the malignant phase of essential hypertension. On the other hand, nerve-cutting operations have succeeded in lowering arterial pressure at least temporarily in patients whose primary trouble was glomerular nephritis, that disease does not

contraindicate operation, no matter how bad the urine appears, if uremia is absent and hypertension dominates the clinical picture

MODERN METHODS USED IN FINDING PULMONARY TUBERCULOSIS AND TREATMENT OF THE ASYMPTOMATIC CASE

PHILIP H PIERSON, M D , F A C P *

It is of interest to note the progress that has been made in the program for finding cases of tuberculosis, especially since the founding of the National Tuberculosis Association and the American Trudeau Society. Their object has been the education of the public and the practitioner of medicine to the presence of this disease, methods of finding it, and its control through isolation and scientific treatment. Reporting of the disease, availability for sputum examinations, care of the undernourished child who was thought to be tuberculous, following up of the contacts of known cases, tuberculin testing of children and part of the adult population, with x-rays of the reactors, have been steps in this forward march. But still all too many cases were first discovered in a moderately or far advanced stage of their disease. This was at least in part due to the fact that patients and physicians waited for the classical symptoms of tuberculosis before taking sufficient steps to establish the diagnosis. Physical signs were relied upon until recent years and were pitifully absent even in moderately advanced disease. With the development of rapid strides in x-ray technic and interpretation, it was found that tuberculous and nontuberculous disease, including cancer and heart disease, could be suspected long before symptoms were experienced by the patient.

RAPID SCREENING METHODS—HISTORICAL DATA

One of the first mass surveys with the fluoroscope was conducted at the University of Munich in 1927, when 5707 students were examined. During 1930, 3000 students at the University of Lwow were examined by the fluoroscope or x-ray films and since then it has become compulsory for all entering students. Photographing the fluoroscopic image dates back to 1895, less than six months after Roentgen discovered the x-ray, when Blever in England developed a technic for this procedure. In 1911, Caldwell in this country "clearly demonstrated that the camera recorded much more than the eye could see on the fluorescent screen." It was de Abreu of Brazil "who deserves the credit for putting

From the Department of Medicine, Stanford University School of Medicine, San Francisco, California

* Clinical Professor of Medicine, Stanford University School of Medicine, Chief, Department of Tuberculosis, Stanford Clinic and Stanford Service, San Francisco Hospital

this method on a firm basis for mass thoracic survey work." Since 1936 he has used this method in mass surveys in Brazil, Argentina, Chile, Uruguay and several European countries. Lindberg and Hirsh in this country received their stimulation in this work from de Abreu.

Is it any wonder then that even before the outbreak of World War II a great many groups of our population were being x-rayed on photo-fluorographic films. Along with these small films, sensitized paper films 14 by 17 inches were perfected and they were manufactured in rolls thus making developing and storage simpler and more economical than the celluloid films of the same size. They have been used perhaps most extensively by Edwards and his co-workers in New York City. Of the photofluorographic films there are two sizes, the 4 by 5 inch single or 4 by 10 inch stereoscopic films and the 35 mm films which are manufactured in rolls. The object of all these methods, which supplemented the regular 14 by 17 inch celluloid films, was low cost per exposure, ease and speed of developing and interpreting, economical storage and a reasonably good picture which would show significant disease.

INTERPRETATION AND ACCURACY

Naturally, it takes some time by even skilled observers to acquire proficiency in the art of interpreting these small films as it likewise does in the correct reading of the fluoroscopic image and 14 by 17 inch celluloid films of the lungs and heart. The fluoroscopic films are taken at a distance of 36 inches, one-half the distance used in taking regular sized films, and allowance must be made for magnification of the heart shadow and the granular appearance of small films when enlarged for reading. It is only to be expected that those who have perfected themselves by experience in the use of one type of film will become more adept in that method and prejudiced in its favor.

The interpretation of these paper 4 by 5 inch and 35 mm films then, must be done by those with experience and not by the individual who only occasionally reads regular x-rays of the chest. Considerable discredit can be cast on this method unless these precautions are carefully followed. Because of the simplicity in technic of these new procedures it has been possible to take about 200 pictures per hour (60 to 100 films per hour is a more reasonable goal). With the fluoroscope considerable speed can be developed in screening a large number of persons but after an hour or two of this rapid work the eyes of the operator become fatigued and he must rest in order to continue to do good work.

From all this it can be seen that our approach to tuberculosis has made significant progress for now we are able to x-ray large groups of apparently healthy individuals in a short period of time, at a cost which is not prohibitive and with pictures which correlate very well

with the standard films * Douglass, Birkelo, Harmon and Vaughn in 1940 estimated that the accuracy of 4 by 5 inch films compared with 14 by 17 inch standard films was 97.4 per cent, and Bridge put the figure at 98.5 per cent. Spellman, in the same year, estimated that 35 mm films were about 90 per cent accurate. There is so much difference of opinion by observers reading 14 by 17 inch films that a true comparison of accuracy of different methods is impossible at the present time. In all these methods it is necessary to remember that we are dealing only with a screening method and that whenever there is a question of disease a standard film should be taken to verify the condition. In surveys it has been found that between 2 and 5 per cent of the persons must be checked in this manner.

In the order of their accuracy it has been quite generally agreed that we should put, first, stereoscopic 14 by 17 inch celluloid film, second, single 14 by 17 inch celluloid film, third, 4 by 5 inch stereoscopic or 14 by 17 inch paper film, fourth, 35 mm films, and fifth, the fluoroscopic study. The last is in this position possibly because of the inability for the eye to register all that the camera does and because there is no permanent record but it has the advantage in the hands of skilled observers of viewing the chest in many angles, thereby seeing behind the ribs and mediastinum, viewing the different chambers of the heart and seeing the motion of the diaphragm. Small faint infiltrates are sometimes missed. Its ease of use and lack of expense, however, offer much in its favor for the experienced man in his private practice.

COST DATA

The cost of taking paper 14 by 17 inch films, 4 by 5 inch and 35 mm celluloid films has been estimated as follows (figures probably do not include the equipment)

Paper films Mercer in 1941 stated that the cost was 25 cents per man x-rayed.

Four by 5 inch stereoscopic films Long in 1941 stated that their cost averaged 54 cents per man x-rayed and 63 dollars per case of tuberculosis found.

Thirty-five mm films Mercer stated in 1941 that the cost was 1 cent per man. Perhaps some of these figures do not include the cost of assembling people and filing the films.

Miniature films (size not stated) Galbraith stated in 1941 that the cost per recruit examined was 5 or 6 pence and that this covered the retakes on 14 by 17 inch standard film, plus the cost of processing, wages of staff and salaries of specialists.

Fluoroscopic examination Von Allman in 1942 stated that the cost per person fluoroscoped was 42 cents, the cost of each person needing

* A conservative estimate of the number x-rayed by miniature films in the armed forces from 1942 to 1944 was 16,000,000, and by the United States Public Health Service, particularly in war industries, was 2,000,000 in the same period.

medical care was \$31 16 and the cost of each active case of tuberculosis discovered was \$87 71

POSSIBILITIES OF THE MASS SURVEY IN THE FIELD OF TUBERCULOSIS AND OTHER PULMONARY AND CARDIAC DISEASES

Value of a Method for Determining Mass Morbidity—Whether in times of peace or war it is essential that the health of every man, woman and child be kept at the highest level possible. According to Miller, 31 per cent of the second million called in the draft were unfit for general military purposes and 24 per cent of these were so because of tuberculosis. This group is a representative cross section of the male population between the ages of 21 and 36. The average of many other sets of figures places the percentage of significant tuberculosis as between 1.5 and 2 per cent, with one half of the victims in an active stage, unaware that they had the disease. Edwards in New York City, who surveyed a large group of apparently healthy persons, found rates varying from about 2 to as high as 8 per cent, with one half of them active. Large groups of industrial workers have essentially the same status. We have known for a long time that sickness varies inversely with the economic status. The National Health Survey in 1935-1936 stated that, of the first 2,308,600 persons in this group of urban dwellers, disabling illness of those on relief was 47 per cent higher for acute illnesses, and 87 per cent higher for chronic illnesses than the corresponding rates for families with incomes of \$3,000 and over. There are racial groups in which hereditary lack of resistance, crowded living conditions and low economic status have produced a particular high rate of tuberculous disease.

Now that the mortality rate as a whole has dropped from about 200 in 1900 to 41 per 100,000 in 1943, we have in this x-ray method the opportunity to search out the apparently well persons who have x-ray evidence of tuberculosis, from whose ranks the future deaths from this disease will come. It is possible to survey industrial plants where it is known that the mortality from tuberculosis among unskilled workers is two and one half times greater than among skilled workers and where the morbidity from this disease causes a large number of lost hours from work, and most important allows the victim with the active lesion to infect many of his fellow workmen. It also presents the opportunity of finding patients with minimal infection, so that with proper treatment they may be restored to health and working efficiency. There are many causes for the development of tuberculosis, such as physiological background, nutrition, housing and others, that still must be ferreted out, but the discovery of the early and especially the moderately advanced case will go a long way toward hastening the disappearance of tuberculosis.

Industrial and Insurance Experience—One of the first mass surveys in

this country was that conducted in the small industrial city of Framingham, Massachusetts in 1920-1923. It was found that for every death there were nine active cases and nine arrested cases. This has served as a guide for estimating morbidity. Mortality statistics are quite accurate but, since morbidity rates are dependent upon the reporting of the disease, more definite figures are needed than those of the Framingham study. In 1934 a mass x-ray survey was started in New York City and 400,000 persons were studied. An interesting and instructive comparison of the incidence of disease in the white and colored groups was made. In 1938 the mortality rate was 255 per 100,000 among the Negroes and 41 per 100,000 among the whites. In the Negroes between 15 and 20 years of age, the mortality rate was ten to fifteen times that of the same age white population, yet the morbidity was only two to three times as great, representing a higher case mortality among the Negroes. In individuals over 20, while the death rate among the colored group was three to ten times that of the whites, there were fewer cases of tuberculosis found among the Negroes than the whites, again pointing to a very high case mortality.

Other surveys such as those in the Army, in industrial plants and among pension holders, showed fewer cases of tuberculosis were found among Negroes over 26 years of age. In the New York survey, of 400,000 persons 8731 who had negative x-ray films were re-x-rayed fourteen months later and it was found that the yearly incidence rate was 2.4 annually. This, broken down, showed that the incidence among the whites was 1.3, the Negroes 2.8 and the Puerto Ricans 6.6 per 1000. By checking other sources on about 4000 who did not report for re-x-rays, the annual incidence was found to coincide quite closely—2.2 per 1000.

The Metropolitan Life Insurance Company figures showed an annual incidence of between 2.23 and 2.69 in their employees, in the Army it is 2.1 for whites and 2.56 for Negroes, and in steel workers it was 2.1. Hence, the annual incidence of the disease is determined by the number of persons in a community who serve as a focus of infection. The conclusion is obvious that the morbidity rate is not determined by mortality alone but by the resultant of mortality and annual incidence. The annual incidence among Metropolitan Life Insurance Company employees was 4 per 1000 in 1930, but this figure had been reduced to 0.7 per 1000 in 1941.

These figures on the annual incidence of tuberculosis are presented to show the part played in such a study by mass x-ray methods and also to point out ways which must be found to protect people from tuberculosis.

Sometimes it may be difficult to educate management of industry as to the value of a survey of all their employees. It not only saves lives but it saves money. Sparks reports the survey of 100,000 employees and their relatives over a seven year period. Recognition of

tuberculosis resulted in a decrease in the number of days of sick leave from this cause alone of 71 per cent and the saving of a large sum of money

Use of the Mass Survey in General Hospitals and Prenatal Clinics.—Another use of mass x-ray surveys is in general hospitals. Only to mention two studies, that at the University of Michigan by Hodges, and the one in Chicago by Tucker and Babcock, is most instructive. In the former, every patient admitted to the hospital was x-rayed, using the 35 mm film. Of approximately 100,000 films made, 70 per cent showed normal findings, insignificant findings were present in 20 per cent, and significant disease was shown in 10 per cent. Very shortly, Dr Hodges will publish a further breakdown of these figures

At the University of Chicago Clinic, largely a white population, everyone entering the Out-patient Department, about 15,000, was fluoroscoped. It was found that 4.1 per cent of those examined had reinfection tuberculosis, 1.43 per cent being active cases and 2.74 per cent inactive cases. At the Provident Hospital, Chicago, a Negro institution, 25,000 patients were fluoroscoped, 4 per cent were found to have reinfection tuberculosis, of which 2.6 per cent were active cases. These patients, of course, represent a group of people who are sick but their complaints were surgical and medical and an effort was made to exclude those who knew they had tuberculosis. The above figures are quite striking and serve two purposes: (1) they suggest that the bizarre symptoms usually present in these cases might be reflex phenomena resulting from the latent or active tuberculosis, and (2) they lead to an early suspicion of tuberculosis. The latter is significant because a study of the lungs might normally be delayed several days (an average of 15.5 days in the medical wards of another large county hospital service). When it was known that the patient had pulmonary tuberculosis proper therapy was started at once, often saving the patient immediate operation. Suspicion of the presence of tuberculosis prompted immediate isolation so that other patients, nurses and interns were protected. Until this procedure of routine entrance x-rays was installed at the University of Michigan there was a higher incidence of primary tuberculosis among the nurses working in the general hospital than during their training on the tuberculosis wards where strict precautions were routine.

Mass surveys of the nurses and interns themselves have contributed materially to the finding of cases at a very early period, thus reducing materially the incidence of active disease.

Mass x-ray surveys have also been made in prenatal clinics. Dr. Ianne was a leader in this and found in 1939 by tuberculin testing and x-raying all reactors that 1.7 per cent of the reactors (41 per cent) showed clinically active tuberculosis at a time which was most crucial for the mother and the unborn child. By proper treatment there was no spread of the disease during or after pregnancy.

Summary—We have a screening method in the x-ray, be it standard sized or miniature films or fluoroscope, which will lead to the suspicion, at least, of tuberculosis in a large cross section of our population. When found by this method more than 50 per cent of the cases are minimal and generally respond promptly to proper therapy. Knowing that between 0.5 and 2 per cent of our population has active tuberculosis without symptoms should so intrigue our medical profession that fluoroscopy will be carried out or x-ray films will be taken routinely. The physician should make his own office a unit for mass surveys.

I have not mentioned the x-ray study of all the contacts of known cases of tuberculosis. This should never be neglected, for many cases of the disease are found in the immediate environment of the known case, they may represent the source of this case or the result of infection from it.

THE TREATMENT OF THE ASYMPTOMATIC CASE

As has been stated in the foregoing paragraphs, mass x-ray surveys are a screen. Not everyone who has a shadow in his miniature x-ray film has tuberculosis. A study of each case must be undertaken at once to establish the diagnosis definitely. First a 14 by 17 inch x-ray film (preferably stereoscopic) should be made. This may show that the original suspicion was erroneous and that no disease is evident, or it may go so far as to show more extensive disease even with cavitation where none was originally suspected. The type of shadow and its consistency may likewise suggest other possible pulmonary diseases. I cannot emphasize too strongly here that cancer of the lung to be treated successfully surgically must be recognized in an early stage. Hodges found that out of 167 proven pulmonary lesions discovered by photofluorography in a three-months' period, 10 per cent were due to neoplasm.

After a satisfactory film of the chest has been made a careful history should be taken, questioning the patient concerning (1) fatigue, (2) digestive disturbances, (3) cough and (4) loss of weight. Sometimes one or more of these symptoms may have been present but not sufficiently prominent to attract attention. After a careful physical examination a tuberculin test should be applied (1st and 2nd strength purified protein derivative [PPD] or 0.1 mg. of tuberculin [OT] intracutaneously). A negative reaction is of perhaps more value than a positive reaction. If there is no reaction to tuberculin an acute or chronic nonspecific respiratory infection may be the cause of the shadow. An increasing prevalence of coccidioidomycosis is being discovered, and a skin test, if positive, or serologic tests may be carried out to determine its presence. Other fungous diseases produce shadows resembling tuberculosis. If the patient has sputum it should be examined preferably by concentrating three seventy-two hour specimens. If

there is no sputum, gastric lavage should be performed and the contents concentrated and studied by smear and culture or guinea pig

If all results are negative as to the etiology of the x-ray shadows, observation is most important. Some shadows due to acute respiratory disease may clear within a few days or weeks. Those that persist are the important ones, and should be considered to be due to tuberculosis until proved otherwise. Because the shadows appear firm in the first x-ray it is far from wise at that time to state that the disease is healed. Knowing that from the ranks of this asymptomatic group some will enter in the active phases of this disease, we should consider each patient with particular care.

Let us consider the possible forms of treatment in three subdivisions

1 **The Patient Whose X ray Shadows Appear Firm and Are Minimal in Extent**—In the first place, this patient should be told the facts about his disease, its possibilities of spread or regression. He should be put on a daily schedule which allows him to continue his work, if not too arduous, not more than eight hours a day. His diet should be outlined so that he receives a balance of the essential foods with a total caloric value suited to his needs in maintaining a weight which is about 5 to 10 per cent in excess of his average. He should be in bed at least nine hours a night and take a restful day off—at least one in seven. Intemperance in anything should be avoided. This I visualize as a 'normal life.'

Every month this patient should be rechecked as to progress and preferably fluoroscoped at each of these visits. If all goes well an x-ray is taken within three months and if favorable his visits may be less frequent—one every two or three months for the balance of that year and at six-month periods thereafter for at least a year or two. He should always be particularly careful if he has an acute respiratory infection, for then a small area of tuberculosis may break down and disseminate bacilli. Monthly specimens of sputum should be examined, and if he has no sputum a gastric lavage every three or four months at least during this first year should be done. Of course, his associates should be x-rayed to determine whether he received the infection from them or has given it to them. All this is facilitated by the public health nurse who is part of a Health Department with a modern tuberculosis program. This will be discussed later. In this group Webster found that 10 per cent had either positive sputum or gastric lavage studies. If so, this patient should be placed in a group which is to be treated more actively.

2 **The Asymptomatic Patient with Minimal or Moderately Advanced Disease and in Whom the Shadows Are Fuzzy and with Indefinite Borders but no Cavity Is Visible**—The same routine of standard (preferably stereoscopic) x-rays, history, skin tests and sputum studies is followed as in the previous group, but in addition the patient should be put to bed. If no other cause is found to explain the persistent disease it is

advisable for him to learn how to live with this more dangerous type of disease. Sanatorium care teaches him these points better than home instruction because he lives the right kind of life twenty-four hours every day. Webster found 54.6 per cent of these patients had a positive sputum or gastric specimen obtained by lavage. If his sputum is persistently positive and the shadows do not extensively clear after two to three months, pneumothorax therapy should be strongly considered. Early collapse therapy where rest has not succeeded often closes unseen cavities and the shortened period of sanatorium care may come within the patient's financial abilities. With such a program many patients can afford three to four months in a sanatorium, as against the many months or years required if the disease becomes more extensive. If the pneumothorax is satisfactory—not limited because of adhesions—and is allowed to produce selective collapse, the patient may continue his treatment at home, remaining of course under strict supervision.

3 Patients Whose X-rays Show More Extensive Disease and the Presence of Cavitation—The same immediate study should be carried out and if it is positive for tuberculosis the patient should enter a sanatorium at once. If, with rest for a month or six weeks, the lesion has not markedly regressed pneumothorax therapy should be instituted, and the regimen outlined previously carried out. The patient should remain until his sputum is consistently negative—or as Willis has quite expressively called it, "positively negative." He may need forms of collapse therapy other than pneumothorax but these should be carried out while he is under close observation in the sanatorium.

The Follow-up—In order that persons who through this survey method are suspected of having tuberculosis may receive prompt care and study, the Public Health Service has formulated the following plan to be carried out everywhere in the county. Selective Service rejectees are all reported to the State and through it to the local Board of Health for further study. In some localities all the men are sent to local clinics and in others those who can afford private care are referred to their physicians for study. Through the help of the local Board of Health and its nursing staff each case can be followed officially, the Health Department receiving reports from clinics or private physicians as to the final diagnosis as well as the presence or absence of tuberculosis in all contacts. In New York City Edwards and his co-workers have been able to study 94 per cent of the rejected men and have found that 8 per cent presented no tuberculosis or that it was clinically compatible with military requirements, and they were sent into the service. Many more in their studies and in the hands of private physicians are at work in industry under proper supervision.

The same general procedure is carried out in large industrial surveys. The State and Local Boards of Health as well as the individuals are notified as to the possibility of tuberculosis and they are sent through the same public or private channels. We, as physicians, should

take this task of diagnosis and treatment seriously for if we do not the Government may take over what now is still in private care. Those who can afford private care of a high standard may avail themselves of it. Those who cannot afford it will be taken care of through the public channels

The strength of any program to find and eradicate tuberculosis is as strong as its weakest link—the proper follow-up. An efficient Health Department with good vital statistics, a sufficient corps of visiting nurses to aid in the follow-up and care of patients, and hospital and sanatorium beds in the ratio of 3 to 4 per death (or in some ratio to the morbidity) from this disease are essential. Many groups must cooperate efficiently to bring about the day when tuberculosis will be a rarity.

Nonofficial (voluntary) agencies, such as the Tuberculosis Associations supported by Christmas Seals, must have an aggressive outlook in this program, often blazing the trail by experiments that cannot be undertaken by the official agencies. They must work most harmoniously with the local and state Boards of Health.

The medical profession must understand the important part it plays in the proper study of each case and in seeing that modern treatment is instituted.

With all this the most recent method of finding tuberculosis—mass x-ray surveys—will go a long way toward eradicating tuberculosis. It is no use struggling to increase the efficiency of x-ray case-finding from 70 per cent efficiency to say, 90 per cent efficiency if (a) the survey cannot be made to cover more than half the population, or (b) if half the cases discovered are permitted to escape from effective supervision.

SUMMARY

An effort has been made to describe mass surveys using miniature x-ray films, paper films and the fluoroscope as means for screening out cases of suspected tuberculosis, nonspecific disease of the lungs, early cancer and heart disease. The method may be applied to approximately ten million inductees into the armed forces, or to every patient who comes into a doctor's office.

A single x-ray film, whether it is the standard 14 x 17 inches or a miniature, is not sufficient to make a diagnosis. It must be supplemented by history, laboratory studies and comparative films. If there is any question about the interpretation of an x-ray film it should be studied by an expert. Specialists should also be employed to read the miniature films and the fluoroscopic study.

Because surveys concern persons with a symptomatic tuberculosis the requirements in tact and diligence to keep them properly cared for are much greater than among persons who have symptoms. Note that most of our social mechanism for control of the tuberculosis problem

has been developed on the experience of patients knowingly tuberculous

In the treatment of the asymptomatic case of tuberculosis the patient must be educated on the possibilities of the disease in himself and on the danger of his conveying it to others. Each case must be individualized—some patients may continue at their work if their disease is well controlled and they have periodic rechecks for an indefinite time. They must live a normal life. Others need sanatorium care for education and intensive treatment but this may be relatively short in duration and expense if the disease is amenable to treatment. Collapse therapy after six weeks' or two months' observation often hastens the healing of the disease.

A well planned and efficient program by official and voluntary agencies, the profession and an educated public is necessary for a successful effort in eradicating tuberculosis.

THE MEDICAL CLINICS of NORTH AMERICA

NEW YORK NUMBER

SYMPOSIUM ON INTERNAL MEDICINE IN GENERAL PRACTICE

INTRODUCTION MODERN TRENDS IN INTERNAL MEDICINE

DURING the past twenty years of my experience as a practitioner and teacher, as well as editor of a textbook, certain trends have become apparent in the field of internal medicine. The reading of the excellent contributions in this number of the *Medical Clinics of North America* serves to accentuate this fact. Internal medicine changes as medical science develops, and sometimes these changes take place with remarkable rapidity. As examples, one thinks immediately of chemotherapy in the field of infectious diseases, and the recent remarkable developments in endocrinology. These changes are so obvious as to hardly be worthy of comment. What I have in mind are rather the more gradual changes in point of view, so to speak, which are noticeable as one follows the trend of medical literature from year to year. Let me briefly refer to some of these trends.

1 *The trend away from emphasis on pathological anatomy to emphasis on pathological physiology*, or to put it in another way the change of interest from structure to function. The brilliant contributions of Virchow and his contemporaries in pathology had an enormous influence on the internal medicine of Osler's time. As a result, Osler's textbook and to a less extent other medical monographs which were published at the turn of the century, gave a great deal of space to the discussion of pathological anatomy. The trend toward physiology was brought about by the rapid advances in physiology and biochemistry. This additional knowledge concerning human physiology, both normal and pathological, greatly widened the internist's concept of disease and put modern therapeutics on a rational basis.

2 *The trend away from emphasis on infectious diseases to chronic constitutional disease*. This trend of course is obvious to every internist and the reason for it is also clear. Infectious diseases have in great measure been brought under control. Chronic systemic disease is still

pretty much an unsolved problem. No doubt the increasing average age of our population is another contributing factor, and in part explains the recent appearance of a number of articles and monographs on geriatrics. The problem of chronic disease becomes increasingly fascinating to the internist, and certainly he approaches it with much more optimism than did the previous generation of physicians.

3 *The rapid development of subspecialties in the field of internal medicine.* We have had gastroenterologists, cardiologists and neurologists for some time past, but during the last few decades a great variety of new specialties have appeared in the field, and many internists are devoting almost their entire time to such subjects as tuberculosis, diabetes, arthritis, allergic diseases and disorders of the endocrines. Personally I believe this is a wholesome trend. However, it is very important for these highly specialized practitioners to maintain their contacts with the whole field of internal medicine. Otherwise they become so narrow in their point of view that their approach to all medical problems is completely dwarfed, and because of their lack of facility and skill in other lines, they lose the proper perspective in both the diagnosis and treatment of their particular specialty.

The rapid development of these subspecialties makes it difficult at times for the general practitioner to discover just what constitutes his domain today in the field of practice. Perhaps the establishment of group clinics will lead to a solution of these confused borderlines.

4 *The rapidly increasing number of laboratory tests.* Such procedures all have their place in modern medicine, but it would seem as though the great multiplicity of these tests in some particular fields, such as liver function, have grown to a point where some birth control were indicated! Several problems arise in connection with modern laboratory studies. One is the cost to the patient, the other, proper understanding and interpretation of these tests by the physician. It is all very well for the internist to be told that the plasma calcium is high and the plasma phosphorus low in osteitis fibrosa cystica, but it is much more important for the physician to know just why these abnormalities have occurred and what significance they have in the handling and treatment of the patient.

5 *The restoration of neurology as an integral part of internal medicine.* For a while it looked as though this important branch would be completely severed from the parental tree! However, the modern tendency is more and more toward an approachment between internal medicine and diseases of the nervous system. In many of our large medical clinics, nervous diseases are now included as a part of internal medicine, and the professor of nervous diseases has the title of professor of medicine. Neurology cannot function without internal medicine. Internal medicine is incomplete without neurology.

6 *The growing emphasis on psychiatry in solving the problems of internal medicine.* This emphasis is observed in the approach not only

to functional disease, but to organic disease as well. The medical students of today are infinitely better equipped in the methods of psychiatry than were the physicians of the last generation. This change in point of view should inevitably lead to better handling of the psychoneurotic patient.

7 *Increasing interest in the social aspects of medicine and the widening field of industrial medicine* The modern physician is becoming more and more interested in the family background of the patient and his home environment. Dr. Henry B. Richardson has just published a fascinating book on the relation of the patient to his family.* More and more the physician is studying the environment of his patient, both at home and in industry, and is finding it a fruitful field for better understanding of the causes of disease. It is because of the writer's own interest in the patient's environment that he is contributing a short article to this symposium on environmental factors in the etiology of rheumatic pain. More careful investigation of home and industry in relation to disease will continue to throw important light on the pathogenesis and treatment of many medical ailments.

ENVIRONMENTAL FACTORS IN THE ETIOLOGY OF RHEUMATIC CONDITIONS

RUSSELL L. CECIL, M D , S c D , F A C P *

It is customary for teachers of medicine to stress the importance of history-taking in the examination of a new patient, and certainly nothing is more important in arriving at an accurate solution of the patient's problems. However, many of us in medical school learn things which we promptly forget to apply in practice. In my own experience, I have been frequently amazed at how little effort has been made on the part of the family physician to explore into the daily habits and environment of the patient in order to locate the cause of his trouble. This is well illustrated in the field of rheumatic conditions. I would like to discuss briefly the importance of environmental factors in relation to arthritis, gout, fibrositis and certain other unclassifiable arthralgias.

Rheumatoid Arthritis.—In the case of rheumatoid arthritis we are dealing with a disease of unknown etiology. Infection is supposed to play an important part, but in my opinion psychic factors are of even greater importance in initiating the original symptoms or in bringing about a relapse. The psychic traumas most frequently responsible are marital unhappiness, the death of a near relative, financial disaster, long-cherished resentment over some real or fancied injury, and loneliness, which may be extreme, even in the most populous communities. One of the commonest predisposing causes of arthritis in women is the long-sustained anxiety, plus the physical exertion, which results from nursing an aged father or mother over a period of months or even years. I have seen several cases of rheumatoid arthritis develop in young wives whose husbands are overseas with the armed forces. One recent rheumatoid patient developed her first symptoms of arthritis the day following the classification of her husband as 1-A¹.

The role of climate in the etiology of rheumatoid arthritis is a very definite one, but a factor which is not well understood. Rheumatoid arthritis is primarily a disease of the temperate zone, but it is not unusual to encounter the disease in subtropical climates. Exposure to dampness and cold has some importance also. A good many young men are developing rheumatoid arthritis in our army. However, just how much of this is due to exposure and how much to psychic trauma it is hard to say.

* Professor of Clinical Medicine, Cornell University Medical College, Attending Physician, New York Hospital, Visiting Physician, Bellevue Hospital, New York City

Osteoarthritis—If psychic trauma is a major factor in the development of rheumatoid arthritis, *physical* trauma is the important predisposing agent in the etiology of osteoarthritis. Indeed, unless the role of physical trauma is appreciated by the physician in his approach to this disease, his therapy will often end in failure. The physical trauma may occur in the form of one single severe episode, such as intra-articular fracture or dislocation of a joint, or it may be a long series of repeated minor insults. Many an old college athlete in his later years pays highly in physical discomfort for the athletic trophies which he won in school and college. The student of rheumatism encounters these cases frequently in private practice. In the clinic one is more likely to find osteoarthritis as the result of falls, accidents and the like. Much more frequently, however, this very prevalent disease is caused by repeated minor injuries. Osteoarthritis of the spine in manual laborers or middle-aged tennis players, osteoarthritis of the hip in truck-drivers and pole-vaulters, osteoarthritis of the shoulder in streetcar conductors, osteoarthritis of the knees in obesity or in old football or baseball stars. In many cases the cause of the osteoarthritis is not at once discernible. Only by careful inquiry and going back into the habits and sports of early life will a basis for the trouble be discovered.

I know of no statistical figures on the relative incidence of osteoarthritis in temperate and in tropical climates. My surmise would be, however, that osteoarthritis, like rheumatoid arthritis, is much commoner in the temperate zone. Certainly the people who have lived hard and exposed lives appear to be more prone to degenerative arthritis than those whose circumstances are more fortunate. The gnarled hands of the farmer come inevitably to mind. I have often noticed how individuals whose work requires constant submergence of the hands in cold water are prone to develop osteoarthritis in later years.

Gout—It is possible for an individual to have a gouty diathesis, with high blood uric acid levels and even the renal complications of gout, without any joint manifestations. However, this is *unusual*. The great majority of gouty patients sooner or later have attacks of gouty arthritis. What interests us for the moment are the environmental factors which are instrumental in bringing on the acute attacks of arthritis. The most important provocations of gouty arthritis are trauma and dietary indiscretions. Undoubtedly the prevalence of gouty arthritis in the metatarsophalangeal joint of the great toe is due in large part to the trauma to which this joint is subjected in walking and in other forms of active exercise. The gouty attack may be precipitated by such minor trauma as an unusually long walk or bicycle ride, an excessive amount of golf or tennis, or even too much lawn mowing. According to Hench the inflammatory reaction in posttraumatic gouty arthritis is usually delayed several hours after the trauma, in this respect differentiating the condition from a true traumatic arthritis in

which the discomfort and inflammatory reaction begin immediately after the trauma

Gouty arthritis is often brought on by dietary excesses, such as occur on birthdays, weddings, Thanksgiving and other holidays. On hunting and fishing trips indiscretions of diet may be combined with trauma, an almost perfect combination of predisposing factors. It is important to remember that surgical operations, transfusions and certain drugs, such as salyrgan, ergotamine tartrate, thiamine hydrochloride, insulin and decholin may provoke an attack of gout.

Fibrositis and Other Unclassifiable Arthralgias—In this group of cases environmental factors play a much more important role than is generally suspected. First of all, we are dealing in the majority of cases with a psychoneurotic patient. This fact in itself explains certain pains which are possibly imaginary. However, many of these patients, while they are nervous individuals, are having real pain in their joints or muscles. One of the commonest of these conditions is *stiff and painful neck*, often associated with occipital headache, a syndrome which Harold Wolfe has termed "tension headache." This condition may result entirely from an anxiety state. Other factors, however, which have to be considered are posture, eyestrain and osteoarthritis of the cervical spine.

Another extremely prevalent form of "rheumatic" pain is *lumbago*, or so-called "back strain." Many of these are referable to protrusion or rupture of an intervertebral disk, a condition in which trauma plays a very important part. Backache of a less severe character may be due to faulty posture or instability of the lumbar spine, but in many such cases the pain is actually due to occupational strain such as carrying heavy bags or suit cases, excessive and strenuous labor or extreme indulgence in sports such as golf, tennis or baseball. Too often, in my experience, back pain which is referable to occupational or other environmental factors is incorrectly attributed by the physician to osteoarthritis of the lumbar vertebrae, especially in those cases in which the radiologist has reported osteoarthritis in this locality. In view of the fact, however, that practically every normal individual over 45 years of age will show some radiographic evidence of hypertrophic spondylitis, the assumption that lumbar pain is referable to these changes is a dangerous one. In cases in which the bony changes are marked, it is safe to conclude that they have some bearing on the patient's symptoms. Nevertheless, it is surprising how many individuals with marked osteoarthritis of the spine are entirely comfortable, and it is also noteworthy that many patients with lumbar osteoarthritis will be relieved of their backache when they cease from certain activities in work or recreation which have been largely to blame for their discomfort. Bad posture is an important factor in the etiology of back pain and should always be carefully investigated in a patient with this complaint. Even when the posture is apparently good, inquiry into the

individual's habits of life may reveal that he is standing too much, sitting in an uncomfortable chair, sleeping on a sagging mattress or wearing improper shoes

One of the commonest causes of backache in elderly people is gardening. Gardening may also be blamed for pain in the knees when the patient assumes a kneeling position for long periods of time without any protection against the hard cold ground. Strange as it may seem, I have known arthralgia in the knees to result from excessive kneeling in prayer. Excessive stepclimbing is another prevalent method of acquiring pain and stiffness in the knees.

Pain and stiffness in the shoulder is usually due to calcific deposits in the subacromial bursa or to so-called peritendinitis of the long tendon of the biceps. Many of these "frozen shoulders" can be traced directly to trauma, either occupational or from overindulgence in sport. *Sciatic pain* is usually the result of pressure at some point in the sacral plexus. Fibrositic pains in the buttocks often simulate sciatic pain and may result from a variety of strains. One of the commonest is driving a car with a stiff clutch or foot-brake. I was recently consulted by a middle-aged woman with sciatic pain. Many questions were propounded in an effort to locate the cause of her disability. All forms of muscle strain were denied. I had given up in despair, went ahead with my physical examination and gave the usual advice concerning rest, physiotherapy, and so forth. As she was taking leave of my office she asked quite innocently if her discomfort could possibly be the result of bowling! Incidentally I know of no sport which can raise more havoc with the back and legs of an elderly individual than bowling, especially if one has not been accustomed to this form of exercise.

CONCLUSIONS

What may we conclude from the foregoing remarks? The most important conclusion is that a large number of trivial pains and aches, as well as some of the more serious ones, result from trauma incurred either in one's daily occupation or from indulgence in some sport. Just as important are the psychogenic factors. Finally we must not omit the pains and aches which result from improper posture when sitting or standing.

When a patient consults me for pain in his arm, the first question I ask is "What are you *doing* with your arm?" If the pain is in the leg "What do you *do* with your legs?" These questions, however, are not enough. Many patients will fail to provide a clue, so the physician must make his questions more specific. Many of these pains and aches which result from environmental factors will disappear almost over night when the cause is removed. Unfortunately there is a large group of patients whose pains result from their occupation, yet who are in no position to change their vocation. In such cases about all one can do is to reassure the patient and give him certain simple

suggestions regarding rest and the use of heat and aspirin which may help him over the rough spots

Psychiatric problems can often be solved by the general practitioner, but in the more difficult cases the neurophysiologist will be needed. After all, one can endure a certain amount of discomfort philosophically if he understands that the condition is not serious and not likely to increase in severity. I have often remarked that a large part of my working hours was consumed in telling patients that they did *not* have arthritis or neuritis, and that the pain in their arm or leg or back was something that could readily be corrected by proper readjustment to their environment.

PRESENT DAY TREATMENT OF NONTUBERCULOUS RENAL INFECTIONS

MEREDITH F. CAMPBELL, M.D.*

When urinary infection is denoted by the demonstration of bacteria in the properly collected specimen, the kidneys and upper urinary tract must be assumed to be involved until adequate examination proves otherwise. It is recognized that often enough the bacterial invasion is limited to the lower urinary apparatus (bladder, urethra, prostate, and so forth) but far more frequently the lower tract manifestations reflect unsuspected and overlooked infection of one or both kidneys. Moreover, the clinical and therapeutic aspects of urinary infection are fundamentally identical whether the patient is four or forty. By custom urinary infections in infants and children have been divorced from infections in adults. Yet the basic considerations are the same with the striking exception that in early infancy the maintenance of nutrition must sometimes take precedence over direct chemotherapeutic attack on the infection itself.

DIAGNOSTIC STUDIES

The demonstration of pyuria in the properly collected specimen almost always signifies urinary infection. amicrobic pyuria is rare but in recent months several series of cases of this clinical entity have been recorded. Some observers believe the condition is due to virus infection; doubtless it is often unrecognized urinary tuberculosis.

Collection of the Urine—Pyuria having been demonstrated as an accidental finding in patients with unsuspected asymptomatic urinary infection, or by routine urinalysis in patients believed to have acute or chronic infection, further laboratory study of the urine is indicated. Here the proper collection of the urine specimen is of paramount importance. When urinary infection is under study in the female, an accurate estimation of pyuria and identification of the bacterial invader demands that the specimen be taken by catheterization whether the patient is newborn or aged. No amount of scrubbing of the female genitalia will permit the passage of a bacteriologically uncontaminated specimen. As a rule, in the male, a satisfactory specimen can be obtained without catheterization: the prepuce is widely retracted, the glans penis and meatus are well washed with oxyvanide or bichloride of mercury 1:500 after which the patient voids. When a small amount of urine has been passed, the sterile vessel to collect the specimen is

* Professor of Urology, New York University College of Medicine, New York City.

introduced into the voided urinary stream. Unless this procedure can be carefully carried out, aseptic catheterization is employed.

Analysis of the Specimen—The properly collected fresh or well-shaken uncentrifuged specimen is then analyzed routinely with special emphasis on the microscopic examination. Normally the kidneys excrete 300,000 to 500,000 leukocytes in a twelve-hour period and this may cause the appearance of 1 or 2 cells per high power field of uncentrifuged urine. More than 3 to 5 cells per high power field may be considered of clinical importance. No cell should be identified as a pus cell which does not show the lobed polymorphic nucleus, which is readily demonstrable by the addition of a drop of 1 per cent acetic acid to the slide preparation. Too often desquamated epithelial cells are reported as pus cells. The estimation of the pus cell content by examination of centrifuged urine specimens is wholly misleading, but if fresh unsedimented urine is periodically examined during the illness period, satisfactory deductions as to therapeutic success may be made.

Identification of the Invading Organism—Bacteriologic investigation is accomplished by urine culture or by Gram stain of the sediment of a centrifuged specimen. The correct identification of the invading bacteria is of paramount importance in the selection of chemotherapy (see tabulation). For example, on a bacteriologic basis, mandelic acid compounds and sulfonamides can be employed almost interchangeably, except that the ammoniogenic *proteus bacillus* is rarely eradicated by mandelic acid compounds yet is readily susceptible to sulfonamide therapy. *Streptococcus faecalis*, the so-called enterococcus, is decidedly sulfonamide-resistant but usually responds favorably to mandelic acid therapy. Penicillin is effective against most gram-positive coccal infections of the urinary tract but is inert against organisms of the *colon-typhoid* group, *proteus bacillus*, and *enterococci* (*Streptococcus faecalis*)—bacteria which commonly invade the urinary tract. In short, rational treatment of urinary infections demands that the etiologic organisms be precisely identified, and when intensive chemotherapy fails to cure the acute disease within two weeks or chronic urinary infection within one month, a thorough urologic investigation is indicated, at which time a more precise anatomic diagnosis usually can be made. Urinary infection persisting more than one month may be considered chronic. In persistent hyperacute renal infections showing no improvement with four to six days of intensive medicinal treatment, complete urologic examination is also indicated.

TREATMENT

With the foregoing basic considerations in mind, we proceed to the active treatment of the infection and this will be guided in considerable measure by the severity of the disease and whether acute or chronic. In most instances of acute infection, the patient can take the indicated dose of antiseptic by mouth but in some critically ill, de-

hydrated patients, medication must be administered intravenously, particularly when there is persistent vomiting. As a rule the chosen antiseptic should not be given continuously for more than eight to ten days; failure to observe this dictum accounts for many instances of drug intolerance or severe reaction. It is essential in the treatment of both acute and chronic infection that free bowel elimination be maintained, at least one copious movement per day. This usually means that a laxative must be administered, in acute renal infection repeated colonic irrigations, using large amounts of water (7 to 10 gallons) are particularly beneficial. Demonstrable focal infections should be drained or eradicated; yet, in practice, careful search usually fails to reveal the primary bacterial focus.

Known obstruction along the urinary tract should be counter-attacked as well as possible (catheter, dilation, and so forth) and compatible with the condition of the patient, and eventually eradicated when the clinical condition permits.

It is a urologic axiom that urinary obstruction predisposes to the development of infection and, once infection is established in the presence of obstruction, the infection can rarely be eradicated until the obstruction has been eliminated. Yet with the advent of the more powerful urinary antiseptics such as mandelic acid compounds, the sulfonamides and penicillin, we are now able to sterilize the urine in many patients with urinary obstruction in whom the formerly employed antiseptics were ineffective. In other words, cure of the urinary infection by the administration of methenamine (urotropin) is presumptive evidence that no important urinary tract obstruction exists. On the other hand, no patient cured of persistent infection by the newer urinary antiseptics should be discharged without the benefit of a satisfactory examination of the upper urinary tract by excretory (intravenous) urography. Moreover, an estimation should be made of residual urine as a manifestation of obstructive or neuromuscular vesical uropathy. Most persistent urinary infections are perpetuated by obstruction and/or urinary stasis, and the fact that an infection persisted prior to its eradication by the newer and more effective urinary antiseptics is presumptive evidence that a stasis-producing condition exists. The clinical importance of this observation cannot be overemphasized: if the patient is discharged as cured of urinary infection but with the persistence of an unsuspected obstructive lesion, not only is insidiously progressive and increasingly severe back pressure renal damage permitted to ensue, but the patient is more likely to suffer recurrent infection because of the predisposing factor of urinary obstruction.

Test of Cure—No patient should be discharged as cured of his urinary infection until at least two negative bacteriologic examinations of the properly collected specimen (*vide supra*) have been obtained. My preference is urine culture, but several laboratory workers believe that

CHEMOTHERAPY OF NONTUBERCULOUS URINARY INFECTIONS

<i>Sulfonamides</i>		<i>Mandelic Acid</i> (Calcium or Ammonium Salt)	<i>Penicillin</i>
DOSE IN 24 HOURS, GRAMS	Under 2 years, 0.5-0.75	2-4	5000 to 25,000 units intramuscularly q 3h or 50,000 to 100,000 units intravenously (continuous drip) for 2-4 days according to age and size of patient and severity of infection

examination of the gram-stained centrifuged urine sediment is equally accurate and a few believe the method is even more precise than culture. We employ both methods but chiefly culture, occasionally examination of the gram-stained sediment will reveal organisms when the culture is sterile, but in our experience the reverse has been more often true. Unless the urine is sterilized, the patient is not cured and with debilitation and diminution of resistance by colds, fatigue and so forth, exacerbation of the smoldering infection commonly occurs and "acute pyelitis" develops all over again. Such flare-ups punctuate the careers of countless individuals and notably children who recurrently suffer acute and often severe attacks of urinary infection—usually ill-designated as 'pyelitis'—and in whom the indication of recovery from the acute episode is too often based on a negative routine urinalysis report from a commercial laboratory represented by the corner drug store agency. In most of these cases there is likely to be both persisting bacteriuria and unrecognized urinary obstruction, these factors are of paramount importance in the pathogenesis of urinary infection as discussed in the preceding paragraph. Pathologically, the usual renal lesion in so-called "pyelitis" is a diffuse interstitial suppurative nephritis in which the parenchymal involvement far outweighs in importance the pelvic changes.

Chemotherapy—In the chemotherapeutic attack on urinary infection, the functional capacity of the kidneys assumes prime importance, and of scarcely less concern are the reaction of the urine and known intolerance of the patient to any of the urinary antiseptics. Many patients manifest great selectivity in drug tolerance especially as concerns the sulfonamides. In one of my patients, a gentleman of 75 years, as little as 5 grains of methenamine produce marked hematuria and vesical irritability. In another elderly man 20 grains of sulfanilamide precipitated an acute hemolytic crisis which was nearly fatal. Unfortunately the same drug will not eradicate the same type of organism in every individual, but doubtless the usual explanation here is the existence of unrecognized obstruction and/or urinary stasis in the unresponsive patient. Sometimes the selection of the successful drug will be by trial and error, changing until a medication is found which is well tolerated in effective amounts.

Methenamine (urotropin), ketogenic diet, or mandelic acid therapy may be employed when the renal function is good and a urinary acidity below pH 5.5 can be maintained.

Methenamine—Methenamine has lost its popularity since the introduction of newer antiseptics but still has a place when employed in the absence of urinary obstruction and in much larger dosage than commonly given. It is of value when the patient cannot take mandelic acid or sulfonamide compounds. The average daily dose in children is 2 grains per pound of body weight and in adults 1 grain per pound of body weight. Sufficient acidulant, preferably enteric-coated tablets of

ammonium chloride, must be co-administered to maintain the urinary acidity below pH 5.5. A sufficiently accurate estimation of the hydrogen ion concentration of the urine can be made in a few seconds by the use of nitrazine paper and the accompanying color chart (Squibb) obtainable at most drug stores.

Treatment of urinary infections by *ketogenic diet* therapy has been largely replaced by the use of mandelic acid or sulfonamide compounds.

Mandelic Acid—Mandelic acid is particularly effective against gram-negative bacillary infections with the exception of *Bacillus proteus*, here the intense urinary alkalinity caused by the ammoniogenic *Proteus vulgaris* usually defies effective acidulation (see tabulation). Yet the drug is essentially specific against *Streptococcus faecalis* and will be used most often when this organism causes the urinary infection. Mandelic acid is usually administered as the calcium or ammonium salt, as the elixir, or the syrup, and to be effective must be given in large doses and with sufficient acidulant (preferably enteric-coated) ammonium chloride tablets to render the urine more acid than pH 5.5. Most failures in mandelic acid therapy result from inadequate dosage and failure properly to acidulate the urine. An alkaline intake (sodium bicarbonate, milk of magnesia, citrus drinks and fruits, and the like) is to be strenuously avoided during the medication period. The dose of mandelic acid in adults is 10 to 14 gm per day and for children the dose will vary between 0.3 and 0.5 gm per kilogram body weight according to age and digestive (nutritional) factors. Excepting in the combat of *Streptococcus faecalis* infection, and because of the ease with which acidosis is produced in the young, sulfonamides will be largely employed when the patient is an infant or young child.

Sulfonamides—Sulfathiazole and sulfadiazine merit the chief consideration as urinary antiseptics today. Sulfathiazole is particularly effective against *Staphylococcus aureus* and *albus*, *colon bacilli* and *Streptococcus faecalis*, and this action is favored by acid urine which, unfortunately, predisposes to the formation of and urinary tubular obstruction by acetylated sulfathiazole crystals. The dose of sulfathiazole and sulfadiazine in children is 0.25 gm per kilogram of body weight, and in adults an initial dose of 4 gm per day (for two or three days), then 2 gm per day for six days. An equal amount of sodium bicarbonate is given to alkalinize the urine to prevent intratubular deposit of acetylated sulfonamide crystals. During sulfathiazole or sulfadiazine therapy in adults, a daily excretion of at least 1000 cc must be maintained, preferably 1500 cc, and any less excretion with a twenty-four-hour intake of at least 2500 cc suggests renal injury by the drug or crystalline urinary obstruction especially in the renal tubules. Renal or ureteral pain and hematuria also suggest complicating crystallization and unless, with the drug stopped, renal excretion increases in twenty-four hours, ureteral catheterization and

ureteropelvic lavage to eliminate obstruction by crystal deposit should always be considered and in some cases is imperative. Delay in this has accounted for many deaths. In a patient of ours with sulfathiazole anuria and uremia, the entire upper urinary tract on each side was so filled with and occluded by crystals that it became necessary to perform ureteropyelostomy to establish renal drainage.

Sodium sulfathiazole can be administered intravenously in high dilution (1:500) as an infusion.

Sulfadiazine is especially effective against the colon bacillus, proteus bacillus, most streptococci, less so against staphylococci, and produces untoward reaction in fewer patients than do the other sulfanomides (10 to 15 per cent). The dose and special considerations of its administration have been given in the preceding paragraphs. Sodium sulfadiazine can be given intravenously in the same manner as indicated for sodium sulfathiazole.

Sulfanilamide, sulfapyridine, sulfamerazine, sulfacetimide and succinylsulfathiazole have not proved as satisfactory for general clinical use as sulfathiazole and sulfadiazine. Sulfaguanidine is but slightly excreted through the kidney and is used only for its bacteriostatic effect on intestinal flora.

Chemotherapy in Acute Urinary Infection—The chosen drug is administered for seven or eight days unless unfavorable reaction to it develops. After a week of medication a rest of three or four days is given at the end of which time an aseptically collected specimen of urine is examined. If infection persists, the therapeutic course is repeated perhaps with a change of medication, and a similar bacteriologic recheck is made. If there is still infection after two or three weeks of such periods of intensive chemotherapy a complete urologic examination is indicated which is likely to reveal obstruction or, in some instances, surgical renal pathology which must receive appropriate instrumental or operative therapy.

Chemotherapy in Chronic Urinary Infection—If favorable response to the bacteriologically indicated chemotherapy is not achieved in four weeks of intensive treatment, a complete urologic examination is indicated and will usually demonstrate uropathology to be treated by combined instrumental and chemotherapy or combined surgical treatment and urinary antiseptics.

When the patient—infant or adult—clinically manifests persistent hyperacute urinary infection (renal) after four to six days of intensive medical therapy, a complete urologic examination is indicated, infected hydronephrosis, fulminating massive or focal renal suppuration, perinephritis, perinephritic abscess, pyonephrosis, or other grave surgical condition is likely to be revealed. Here treatment is often operative together with chemotherapy plus blood transfusions.

Neoarsphenamine—Neoarsphenamine has been of considerable value in the past in the combat of *Staphylococcus aureus* urinary infec-

tions, especially as persistent bacteriuria. Today this use of the drug has been replaced by penicillin, the administration of which is far safer, and the therapeutic results obtained with it in the staphylococcal and most diplococcal infections are more immediately dramatic.

Penicillin—Penicillin has been employed in a limited number of cases of nontuberculous urinary infections and has been phenomenally successful in most patients with streptococcal and staphylococcal pyelonephritis, uncomplicated by colon bacillus infection. In several instances, the penicillin eradicated the gram-positive organisms but had no effect on the gram-negative bacilli. The previous tabulation indicates the bactericidal activity of penicillin. In most adults an intramuscular injection of 25,000 units every three or four hours is given for three or four days. At the end of this time, bacteriologic recheck of the urine will indicate whether further medication—penicillin or sulfonamide or combined therapy—is needed.

SUMMARY

In the foregoing paragraphs attention has been directed to the basic considerations in the treatment of nontuberculous urinary infections in patients of all ages, the details of administration of the various urinary antiseptics have not been discussed since full description is usually given on the commercial package. In at least half of the cases of acute urinary infection and in most instances of chronic urinary infection, complicating pathologic changes—notably obstruction—require special consideration and treatment in addition to chemotherapy. In short, in only a third to a fourth of all cases of nontuberculous urinary infection does chemotherapy alone achieve full benefit for the patient. No patient should be discharged as cured of infection until examination of at least two properly collected specimens by culture or microscopically is negative. If this dictum is observed, the incidence of so-called "recurrent pyelitis" will be infinitely reduced and an inestimable amount of renal damage will be prevented.

PENICILLIN VERSUS SULFONAMIDE THERAPY

LT COLONEL A. ALLEN GOLDBLOOM AND MAJOR EMANUEL H. NICKMAN
MEDICAL CORPS, ARMY OF THE UNITED STATES

In the late 1930's, when sulfonamide therapy came into general usage the medical profession as well as the general public felt that it would be a panacea for bacterial as well as other infections. Its field of usefulness has now become definitely defined and its capabilities and limitations now generally known. With the advent of penicillin a great wave of enthusiasm for it theoretically swept sulfonamides into disuse. It was felt that penicillin could do anything that the sulfonamides could do and do it more efficiently. Fortunately, the drug was not available at that time except to those who could study its properties under controlled conditions. This has prevented indiscriminate usage with resultant misconceptions and has made for a more rapid crystallization of thought with regard to its field of usefulness.

These studies have shown that

- 1 The antibacterial activity of sulfonamides and penicillin are similar in effect against gram-positive and certain gram-negative organisms, in general penicillin being by far the more efficient and the less toxic.

- 2 Certain specific infections are benefited by sulfonamides and not by penicillin, and vice versa.

- 3 When there are like indications for sulfonamides and penicillin, one may be substituted for the other under the following circumstances: (a) drug-resistance or drug fastness, (b) nonavailability of the agent of choice, (c) in the presence of contraindications to the agent of choice.

- 4 Penicillin and sulfonamides, under certain circumstances, may be synergistic in action, as is suggested by recent investigations with animals which have demonstrated that when sulfonamides and penicillin are given together the protective effect is greater than when each is given separately.¹

Many investigators have compared the therapeutic response of penicillin and sulfa products. They have almost invariably reported the superiority of the former both in vitro and in vivo. Fleming^{2,3,4} showed that crude penicillin was four times as efficient a bacteriostatic as sulfathiazole and twenty times more powerful than sulfapyridine when used against *Streptococcus pyogenes* and *Staphylococcus aureus* in human blood. Hobby, Meyer and Chaffee⁵ working with hemolytic streptococci in broth cultures also reported penicillin to have a greater

From the Medical Service, Station Hospital, Camp Kilmer, New Jersey. John M. Tamraz, Colonel, Commanding.

antibacterial effect than sulfathiazole. Both were bacteriostatic, but penicillin alone caused a reduction in the number of organisms. Rosenberg and Arling⁶ reported recovery in seventy out of seventy-one cases of meningitis caused by the meningococcus, *Streptococcus hemolyticus*, *Streptococcus viridans* and pneumococcus treated with penicillin. This series represents a better result than is ordinarily obtained with sulfonamide therapy, however, our own experience indicates that excellent results can be obtained with the latter alone. In an as yet unpublished group of fifty-eight consecutive cases of meningococcal meningitis treated only with sulfonamides complete recovery occurred in every case.⁷

Abraham and his co-workers summarize the advantages of penicillin over sulfonamides as follows: (1) It is influenced only slightly by the number of bacteria to be inhibited. (2) It is not antagonized by hydrolytic break-down products or pus. (3) It combines low toxicity to cells with powerful bacteriostatic action. (4) Its action is stronger.

In spite of the advantages of penicillin over sulfonamides as the therapeutic agent of choice in those diseases in which either could be used, certain practical considerations present themselves. These are: (1) the present greater availability and lower cost of sulfonamides, and (2) the ability to administer sulfonamides by mouth as compared to penicillin, which must be given parenterally. While these considerations by no means preclude the practical employment of penicillin, they do limit its usage.

We feel that at present and until it is readily available penicillin will find its greater application in life-endangering infections, in those conditions which are sulfa-resistant, and where the use of sulfonamides is contraindicated.

CASE REPORTS

A series of eight cases, all of which were life endangering, is presented in the accompanying table. In the first and second cases penicillin alone was used because sulfonamides were contraindicated. Cases III to VI inclusive were sulfa-resistant, penicillin being administered secondarily. Cases VII and VIII represent failure of both sulfa and penicillin therapy.

CASE I—Rheumatic Fever, Bronchopneumonia—This white man, aged 26, was in good health until a few days before he was admitted to the hospital on March 12, 1944, when he became ill with generalized malaise and fever. On the day after admission he developed a generalized erythema associated with arthralgia of the lower extremities. Arthralgia became migratory, low grade fever persisted, endocardial and myocardial changes were noted. A diagnosis of rheumatic fever was made on the basis of the above findings.

Seven weeks after the onset of rheumatic fever his temperature suddenly became septic in type and rose to 104.4° F. Marked orthopnea was present. Physical examination and x-rays indicated a bilateral basilar bronchopneumonia. Sputum organisms were predominantly pneumococci. He was given penicillin,

SUMMARY OF CASES TREATED WITH PENICILLIN (SODIUM SALT)

Case	Age	Diagnosis	Infecting Organism	Total Dosage in Units	Method of Administration	Days Treated	Result	Comment
I	76	Rheumatic fever Pneumonia, broncho-	Diplococcus pneumoniae	480,000	20,000 u q3h I.M.	4	Failure Recovery	Sulfonamides not given, contraindicated
II	37	Nephritis, acute glomerulonephritis	Diplococcus pneumoniae	100,000	10,000 u. q3h I.M.	1½	Recovery Recovery	No reactions to penicillin. Sulfonamides not given, contraindicated.
III	37	Pneumonia, lobar Septicemia	Strep hemolyticus	1,161,500	20,000 u q3h I.M.	6	Recovery	No reactions to penicillin Sulfonamides ineffective.
IV	38	Endocarditis, subacute bacterial	Strep viridans	2,545,000	10,000 to 20,000 u q3h I.V. 10,000 to 20,000 u q3h I.M.	7	Blood cultures negative Partial recovery	No reactions to penicillin. Sulfonamides ineffective
V	22	Cellulitis	Staph aureus	745,000	20,000 u q3h I.M.	4	Recovery	Sulfonamides ineffective. No reactions to penicillin
VI	23	Meningitis	Diplococcus pneumoniae	1,295,000	Intrathecal, I.V., I.M.	8	Recovery	Sulfonamides ineffective No reactions to penicillin Initial intrathecal dose of penicillin 50,000 u., then 10,000 to 20,000 u daily I.M. injections of 25,000 to 10,000 u q3h Only 2 I.V. injections given.
VII	34	Brucellosis	Brucella melitensis (?)	1,000,000	20,000 u q3h I.M.	6	Failure	Skin test with Brucella antigen strongly positive in all dilutions. Penicillin and sulfonamides ineffective. No reactions to penicillin
VIII	21	Tuberculosis, pulmonary	Micobact. tuberculosis	300,000	15,000 u q4h	3	Failure	Penicillin and sulfonamides ineffective No reactions to penicillin

20,000 units every three hours intramuscularly for four days (total 480,000 units) Arrest of the pneumonic process ensued Fever dropped by lysis to normal within seventy-two hours

Cardiac and joint signs and symptoms were unaffected by the penicillin Subsequently, these improved under salicylate and digitalis therapy

CASE II—Acute Glomerulonephritis, Lobar Pneumonia—This patient, a white man, aged 37, was admitted to Station Hospital, complaining of coryza, nausea, vomiting and painful and diminished urination He gave a history of prolonged exposure to inclement weather several days before admission

Signs of acute glomerulonephritis and congestive heart failure were manifest There was almost complete anuria, albuminuria and hematuria, enlarged and tender liver, peripheral edema, cardiac dilatation and a mitral murmur heard at the base of the heart and not transmitted Almost simultaneously physical examination showed signs of lobar pneumonia This was confirmed by x-ray and by the presence of innumerable pneumococci in his sputum

In view of the patient's anuria, sulfa therapy was considered to be contraindicated, and a course of intramuscular penicillin, 10,000 units every three hours, was instituted Pneumonic phenomena and fever subsided within thirty-six hours Alarming kidney and cardiac signs also subsided within this period, but for six weeks thereafter there was a slightly elevated pulse, barely palpable tender liver and a nontransmitted mitral murmur Penicillin, of which a total of 100,000 units was given, was discontinued immediately after the acute symptoms had subsided

Physical examination two months after admission showed no heart or kidney damage. No therapy other than penicillin and supportive measures was used in this case

In Case I the patient had a severe rheumatic fever with myocardial and valvular changes When he developed a complicating bronchopneumonia with signs of acute decompensation, it was felt that he would not survive the double infection Sulfonamide treatment of the pneumonia was not given because of its reported ill effects in acute rheumatic fever Penicillin proved completely effective in curing the pneumonia but had no effect whatsoever upon the course of the rheumatic infection

In Case II we were confronted with a patient with acute cardio-renal failure as well as lobar pneumonia It was obvious that sulfonamide therapy could not be employed to treat the pneumonia because of the anuria Penicillin was promptly started with very satisfactory results, not only in the pneumonia for which it was primarily intended but also in the acute glomerulonephritis The acute severe signs of the latter were under control within seventy-two hours The beneficial effect of penicillin in the latter instance was probably due to kidney excretion of penicillin of higher antibacterial titer as reported by numerous investigators ^{8, 9, 10}

While the satisfactory response of pneumococcal pneumonias to sulfonamides is well known, the two cases presented illustrate the importance of penicillin when the use of the former is contraindicated

CASE III—Septicemia—A male patient, aged 37, was admitted to the hospital complaining of chills and fever Physical examination was negative except for a

moderately reddened pharynx and poor oral hygiene. Dental x rays showed root abscesses around four teeth. Blood culture was positive for *Streptococcus hemolyticus*, Type 17.

It was deemed advisable to begin sulfadiazine therapy before attempting the removal of the abscessed teeth. The drug was given in two courses, one of eleven days averaging 6 gm of sulfadiazine daily, and again, after an interval of five days, in a second course of nine days, averaging 5 gm daily.

In spite of the above medication two positive blood cultures were obtained during the course of treatment, nor did the sulfadiazine eliminate the fever which continued to be of an irregular low grade type with occasional septic exacerbations fluctuating between 98 and 105.2 F. The patient was weak and cachectic and had a yellow waxy pallor.

On May 29 sulfadiazine was discontinued and penicillin started. The patient was given 20,000 units intramuscularly every three hours for six days and a diminishing amount for three additional days. A total of 1,161,500 units was given. A remarkable improvement was noted within twenty-four hours after starting penicillin; the patient expressed a feeling of vitality and well-being, was hungry and cheerful, his temperature was normal, and blood culture was negative. Improvement continued uninterruptedly until his discharge.

On June 1 four abscessed teeth were extracted. No clinical or febrile reaction ensued. All blood cultures after May 29 were negative.

The patient was discharged cured on June 26, 1944.

This patient was given sulfadiazine over a prolonged period during which he showed equivocal clinical and no bacteriologic response to treatment. Under penicillin, recovery was dramatically prompt. Herrell¹¹ feels that sulfonamide compounds are so effective against hemolytic streptococcal infections as to make it unnecessary to use penicillin except occasionally. Our experience with this case, as well as the experience of others,^{12, 13} makes it evident that, when sulfonamide-fast infections of this type occur, penicillin is the therapeutic measure of choice. The euphoria and improvement in appetite which were noted in this case were seen also in other of our patients treated with penicillin. Florey and Florey¹⁴ have made a similar observation.

CASE IV.—Subacute Bacterial Endocarditis.—A white man, aged 38, was admitted on March 1, 1944. His history was negative except for a questionable heart murmur in 1923. About three weeks before admission he began having chills and fever which were of daily occurrence for two weeks before he applied for hospitalization. He had no apparent source of infection other than a mild rhinitis.

A physical examination revealed the patient to be acutely ill, pale and sweating profusely. No petechiae or other evidence of embolic phenomena were present. There was no splenic or hepatic enlargement. A long blowing systolic murmur was heard in the mitral area and transmitted to the left axilla. This murmur was apparently of recent origin, since previous routine examinations over a period of one year indicated no cardiac pathology. The blood pressure was 100/70, the temperature 98.6 to 102.6 F. Three blood cultures taken between March 1 and 6 were positive for *Streptococcus viridans*.

Beginning March 6 penicillin was given both intravenously and intramuscularly for seven days for a total of 2,545,000 units.

Upon completion of penicillin therapy the temperature was normal, blood

culture was negative, and the patient was asymptomatic. Cardiac signs were essentially unchanged except that the mitral murmur could be heard in diastole as well as systole. Hospitalization was continued for one month, during which time blood cultures were negative and temperature remained normal, however, his blood sedimentation rate remained high (125 mm per hr) and the mitral murmur was still present on April 12, 1944, when he was transferred to a convalescent hospital.

Seven months after the onset of his illness the patient was still alive and had sterile blood cultures.

There has been no uniformity in the reported results of penicillin therapy in subacute bacterial endocarditis. In vitro studies¹⁶ indicate that *Streptococcus viridans* is inhibited or destroyed by penicillin, but in concentrations 200 to 1000 times as great as is required for *Streptococcus hemolyticus*. Loewe and his associates¹⁶ have reported seven cases treated successfully with penicillin and heparin, although they claim no permanency of cure. Keefer¹⁷ states that of fifty-five cases reported to the Committee on Chemotherapeutic and Other Agents of the National Research Council only three patients are alive after one year of study. Others^{11, 14, 18, 19} have reported temporary sterilization of the blood or absolute failure.

Further study is obviously required to crystallize opinion with regard to the efficacy of penicillin in this disease. It is possible that high penicillin dosage, as was used in our case and as suggested by the in vitro studies mentioned above, may prove to be the answer to the problem.

CASE V—Cellulitis.—A 22 year old white soldier was admitted to the hospital August 15, 1944, complaining of headache, nausea and pain in the right leg.

He gave no history of recent acute illness, chronic disease, or residence in the tropics. He stated that on the night before admission he had been scratching his right shin in an area which had been hit by a dummy hand grenade one month prior to admission.

Examination revealed an acutely ill and moderately disoriented individual. There was a furuncle on the anterior aspect of the lower one-third of the right leg 1 cm in diameter surrounded by a zone of erythematous induration 8 cm in diameter, tender to touch. Femoral and inguinal lymph nodes on the right side were moderately enlarged and painful. No lymphangitis was present. On admission, the patient's temperature was 102° F., pulse 92 and respiration 22.

Sodium sulfadiazine, 5 gm., and 1000 cc. of 5 per cent glucose in saline were given intravenously immediately. However, the patient's condition became progressively and rapidly worse with lethargy, restlessness and increase in size of the lesion, the surrounding erythematous induration and the regional lymphadenopathy. Sulfadiazine was discontinued and penicillin substituted.

Under penicillin therapy the patient's temperature dropped from 102.2° to 98.8° F. within ten hours and remained within normal limits thereafter. Pain and local pathology remained stationary for two days, but the patient's systemic symptoms were much improved. On the third day, there was a gradual lessening of the local and regional pathologic processes. Improvement continued until on discharge, seven days after admission, the lesion was healed and regional lymphadenopathy was absent. This patient received 20,000 units of penicillin intramuscularly every three hours over a period of four days for a total of 745,000 units.

The remarkably rapid response of this patient to penicillin is in accord with innumerable reports of the successful treatment of *Staphylococcus aureus* infections either with or without bacteremia. It has been noted¹⁵⁻²⁰ that staphylococci are more resistant to penicillin than hemolytic streptococci and that a larger dosage may be indicated in the case of the former. Lyons,²¹ who has a wide experience with penicillin in surgical infections, voices the belief that adequate therapeutic dosage must be given in all cases treated with penicillin, particularly the staphylococcal infections. Unfortunately, the accumulated knowledge of those who have had clinical experience with penicillin is at present insufficient to determine what is adequate and what is inadequate dosage. Further work is necessary in this field before specific criteria can be established for rules of dosage.

CASE VI.—Meningitis.—This patient, a white man, aged 23, was admitted on Jan 5, 1944, in a moribund condition. He was unconscious and cyanotic and had marked nuchal rigidity. Loud bubbling rhonchi could be heard. Several generalized clonic convulsions took place within the first hour of hospitalization.

Subsequently obtained history indicated that he had been injured in a motor cycle accident two and one-half months before admission while on duty in Africa. At that time he sustained a compound comminuted fracture of the right frontal bone and cribriform plate, a simple comminuted fracture of the nasal bone and paralysis of the right third cranial nerve. Following the accident he continued to drain a thin clear fluid from the right nostril. After treatment in various hospitals for two and one-half months he was granted a sick furlough. Three days before his present admission he began having right frontal headaches and dizzy spells to which he paid little heed, as he attributed them to his injury. These symptoms and progressive weakness persisted for two days. On the morning of the third day he was found in bed in an unconscious state.

Physical examination of the patient on admission showed profound stupor, nuchal rigidity, positive Kernig's, Brudzinski and Babinski signs, inexhaustible bilateral ankle clonus and exaggeration of all deep reflexes. There was moderate peripheral cyanosis, innumerable petechiae on trunk and extremities and herpes labialis. The heart was enlarged, the heart sounds of poor quality, the pulse was unperceptible and pulmonary edema was present.

Spinal fluid examination showed *Diplococcus pneumoniae*, Type 14, in abundance.

Sodium sulfadiazine intravenously was given for six hours. During this period all physical signs became worse. Opisthotonos was present, cyanosis became generalized, pulmonary edema became worse with the appearance of abundant frothy mucus in the patient's mouth, and convulsions increased in frequency. It was felt that exitus was imminent.

Penicillin was started at this time, 50,000 units being given intrathecally at once. This was followed by intravenous and intramuscular injections of 25,000 units each. Within twelve hours a gradual improvement in the clinical picture took place. Pulmonary signs, cyanosis, opisthotonos and convulsions were absent; the patient was quieter and the temperature which had been 105° F on admission was now 100.4° F.

Intrathecal penicillin was administered once daily for four additional days in 10,000 to 20,000 unit dosages. Intramuscular penicillin was continued in gradually descending dosages of from 25,000 to 10,000 units every three hours for eight days. The total dosage of penicillin was 1,295,000 units.

The patient regained consciousness on the third hospital day. Improvement was slow but uninterrupted. Pneumococci were absent from the spinal fluid after the sixth day of penicillin therapy.

X-ray examination showed clouding of all paranasal sinuses on the right side. These were treated locally during convalescence. No nasal discharge was present on completion of treatment.

The patient was discharged cured on the seventieth day of hospitalization. There were no sequelae.

This case is illustrative of the life-saving properties of penicillin even when given to a moribund patient. Until penicillin therapy was administered no hope was held for his recovery, in fact, it was felt at the time (January 1944) that the meager supply of penicillin available was being wasted. However, after 200,000 units had been given, its use was rewarded by definite clinical improvement. The initial intrathecal injection of 50,000 units was felt to be warranted despite the fact that dosages higher than 10,000 units were thought to cause reactions.^{22, 23, 24} No ill effects were observed in our case. Priest²⁵ has reported having used intrathecal dosages as high as 40,000 units without significant reactions. Evans²⁶ reported cure of a case of *Staphylococcus albus* meningitis in which 25,000 units were given once daily for six days without producing pleocytosis or other toxic manifestations.

Daily intrathecal injections in our case were supplemented by intravenous and intramuscular injections of penicillin. Early reports of the ineffectiveness of intravenous and intramuscular administration in meningitic infections were based upon the finding that in normal subjects penicillin does not traverse the blood-brain barrier in significant amounts. However, it has been shown that, when the meninges are inflamed, appreciable absorption does occur,²² making these routes valuable supplements to intrathecal administration.

CASE VII—Brucellosis—A white woman, aged 34 years, was admitted May 7, 1944, complaining of fever, malaise, vague generalized pains, marked weakness, chronic nausea, occasional fainting spells, and transitory cyanosis of the upper and lower extremities. This was her fourth hospitalization within a period of seven months.

Her past history was essentially negative except for the ingestion of raw goat's milk in August, 1943. It was shortly after this that she began to feel badly.

Skin tests with *Brucella* antigen were positive in all dilutions. Her opsonic index was indicative of a past *Brucella* infection or chronic brucellosis.

Physical examination and special studies of heart, lungs, gastrointestinal tract, gallbladder and genitourinary tract were essentially negative. X-ray of the dorsolumbar spine showed slight erosion of several vertebrae. Her temperature fluctuated between 98.6° and 100.2° F.

Various types of treatment had been tried prior to her present hospitalization, including the use of Huddleson's vaccine. She noticed no benefit from anything except sulfadiazine, which caused a temporary cessation of symptoms during febrile periods. Symptoms returned upon withdrawal of the drug.

Penicillin therapy was instituted, the patient receiving 20,000 units intramuscularly every three hours for six days. The total dosage was 1,000,000 units. No

improvement was noted either during or following penicillin. The patient was discharged unimproved.

Despite reports of failure in *Brucella* infections, the use of penicillin was felt justified in this case because all other therapeutic measures had been of no avail in controlling the pain and severe debilitating symptoms which this patient had experienced for seven months.

CASE VIII—Pulmonary Tuberculosis—A man aged 21 of Mexican ancestry and native of California, was admitted November 2 1943. He became ill on a troop train three days before admission, with headache, cough and hemoptysis, estimated at 200 cc. He gave no previous history of night sweats, loss of weight, weakness, anorexia, dyspnea, or hemoptysis. He had been well since birth. There were no known tuberculous contacts in his family or among his associates.

Examination on admission revealed flatness, crackling rales, tactile and vocal fremitus in the lower lobes of both lungs. These findings persisted throughout his hospitalization. X rays were indicative of a bronchopneumonia of both lower lobes. Apices were clear.

The patient's course was very stormy with periods of dyspnea which necessitated oxygen therapy, numerous hemoptyses varying in amount from 30 to 400 cc., constant and severe cough productive of small quantities of mucopurulent sputum, and septic temperature fluctuating between 97° and 104.6° F.

During the first two weeks following admission it was felt that the patient had an overwhelming streptococcal bronchopneumonia as suggested by several smears of sputum containing innumerable streptococci. Cultures at this time were negative or uncompleted. Sulfadiazine was administered during this period without benefit. Daily examinations for tubercle bacilli were negative for nine days. Penicillin therapy was started on the ninth day in the amount of 15,000 units intramuscularly every four hours and continued for three days. A total of 300,000 units was given.

Treatment was suspended with the finding of innumerable tubercle bacilli in the tenth and eleventh sputum specimens, since it has been well established that tuberculosis does not respond favorably to penicillin.

Penicillin therapy had no apparent influence on the course of this patient's illness except for the coincidental cessation of hemoptysis and diminution in dyspnea. Physical signs, x ray findings and fever were unchanged up to twenty-one days after penicillin was discontinued.

Little need be said with regard to the two preceding cases. Neither sulfonamides nor penicillin were of any benefit in controlling the infections, both of which were due to gram negative bacilli. Numerous *in vitro* and *in vivo* studies have conclusively shown that penicillin has no effect upon this type of organism. Recent experimental investigations with flavicin,²⁷ streptothricin²⁸ and other antibiotics, however, suggest that the practical treatment of gram negative infections with chemotherapeutic agents is a distinct possibility in the not too distant future.

SUMMARY AND CONCLUSIONS

The foregoing study discusses the relative merits of penicillin and sulfonamides in the treatment of bacterial infections and presents eight cases, all of them life-endangering, treated with penicillin. Penicillin

was remarkably successful in all of the cases in which gram-positive organisms were the etiologic agents *Diplococcus pneumoniae*, *Streptococcus hemolyticus* and *Staphylococcus aureus* were the infecting bacteria in this group

Sterilization of the blood by penicillin was effected in one case of *Streptococcus viridans* infection

Dosage and method of administration was principally by intramuscular injections of 10,000 to 20,000 units at three hour intervals, which we believe to be the most practical method for general use The patient with pneumococcic meningitis received an initial intrathecal instillation of 50,000 units, followed by daily intrathecal dosages of 10,000 to 20,000 units supplemented by intramuscular injections of 10,000 to 25,000 units every three hours Intrathecal injection is essential in meningitic infections treated with penicillin Other methods of administration have only supplementary value

No toxic reactions were encountered in any of the cases presented

We feel that at present, and until it is readily available, penicillin will find its greatest application in life-endangering infections, in those conditions which are sulfonamide resistant, and in those conditions in which the use of sulfonamides is contraindicated

THE USE OF ELECTROCARDIOGRAMS IN MEDICINE

HAROLD J STEWART, MD, FACP*

NUMEROUS papers have been written about electrocardiographic changes in many phases of clinical and experimental medicine and there are many textbooks dealing with the various waves of the electrocardiogram and alterations of them by various diseases which affect the heart directly or remotely. There is need however, for the definition of the use of the electrocardiogram—the recognition of situations in clinical medicine in which it may be expected to yield decisive information of its own or information that will contribute to the clinical picture, in short the integration of the electrocardiogram into clinical medicine. The electrocardiographic interpretation should be considered in association with clinical and other laboratory data. One who reads and interprets electrocardiograms should be a clinician and interested in not only clinical cardiology, but all clinical medicine. The use of electrocardiograms should serve as a check upon the physicians' clinical abilities and contribute to their acuity, rather than to spare them the trouble of careful clinical observations. Especially should this be the case in respect to irregularities of the heart.

Electrocardiograms should be taken under as standard conditions as possible. It is best to have all patients lying down because at later times they may be too sick to sit in a chair, and the two positions might make some differences in the form of the electrocardiogram, for it is known that the position of the body alters the form of the chest lead¹ and of the three standard leads.² Moreover, drinking ice water brings about decrease in amplitude of T_2 and negativity of T_3 without altering T_1 ,³ and after the ingestion of food the amplitude of T waves may decrease.⁴ Recent analysis of large number of electrocardiograms taken on young individuals in whom the physical status was known alters slightly the interpretation of changes which were formerly considered abnormal.⁵

IRREGULARITIES OF THE HEART

What are the situations in which the electrocardiogram gives information and contributes to understanding of a patient's illness? It is fitting that the irregularities should be mentioned first, not only because in them electrocardiograms usually give information which can be interpreted correctly, but also because historically this was the first

From the New York Hospital and the Department of Medicine, Cornell University Medical College, New York City, New York.

* Associate Professor of Medicine, Cornell University Medical College, Attending Physician, New York Hospital, New York City.

use in which the electrocardiogram found wide clinical application. In fact, due to emphasis on irregularities, this phase dominated heart disease for some years. The technic was introduced about the time that the able observer and clinician, Sir James Mackenzie, described auricular fibrillation from polygraphic tracings.⁶ It is not within the limits of this paper to discuss the clinical diagnosis of irregularities, but arrhythmias can still contribute fascinating moments in the study of a sick patient without the use of the electrocardiogram. It is important, moreover, to decide accurately about certain of the irregularities if proper therapy is to be instituted—therapy commensurate with the state of our present knowledge.⁷

First we may consider *premature contractions* or what are loosely called extrasystoles. In most instances they give rise to no symptoms and are discovered by the physician. Other patients, greatly distressed by the irregularity, or by the pause or by the force of the premature contractions, or of the next beat following, may require treatment. In the treatment of these, triple bromides are very effective, after attempts have first been made to discover and eliminate the cause. For their use, electrocardiograms are not first necessary. On the other hand,

Fig 97—(Author's article in Am Heart J, Vol. 1)

if it is contemplated to use digitalis or quinidine, a definite knowledge as to place of origin in the heart of the premature contraction is desirable, and can be obtained only by electrocardiographic technic. For instance, auricular premature contractions can be abolished by digitalis but are not affected by quinidine (Fig 97).⁸ On the other hand, digitalis with one exception is contraindicated in treatment of ventricular premature contractions, while quinidine may be highly effective. The exception concerns ventricular premature contractions that are a manifestation of congestive heart failure and that disappear with adequate digitalization.

The character of this irregularity and the pulse deficit usually permit recognition of *auricular fibrillation* without the use of the electrocardiograph. There are however some instances in which regular beating of the ventricles disguises the character of the arrhythmia (Fig 98). Furthermore electrocardiograms should be taken, if the use of quinidine is contemplated. This applies to chronic auricular fibrillation as well as to its use in paroxysmal auricular fibrillation. This is not the occasion for discussing which cases of auricular fibrillation are suitable for the use of quinidine.

Also it is well to know from the electrocardiographic record that the rhythm is *auricular flutter* because in most instances digitalis is the drug of choice and is more likely to cause reversion to normal rhythm than quinidine. A larger amount may be required than the usual therapeutic one to terminate this rhythm. If success is not achieved by its use, quinidine is occasionally effective.

It is in the other types of paroxysmal tachycardia that exact therapy requires that the rhythm be identified before drugs, such as quinidine and digitalis, are used namely in *auricular*, *nodal* and *ventricular*

Fig 98—In this figure are reproduced the three standard leads and chest lead IVF of an electrocardiogram exhibiting auricular fibrillation with regular ventricular sequence. In this and in electrocardiograms to follow, standardization was such that one millivolt produced 1 cm deflection of the string. Divisions of the ordinates equal 10^{-4} volts. Divisions of the abscissae equals 0.04 second.

paroxysmal tachycardias. In the two supraventricular paroxysmal tachycardias, digitalis is usually the drug of choice and is effective in terminating an attack, but in ventricular paroxysmal tachycardia, digitalis is contraindicated and if used may give rise to ventricular fibrillation and death. On the other hand, in the presence of ventricular paroxysmal tachycardia, the use of quinidine is indicated. Similarly if syncope is due to transient attacks of ventricular fibrillation, the use of quinidine is warranted and digitalis contraindicated. If syncope is associated with complete heart block in the absence of congestive heart failure, there is no occasion to use digitalis but ephedrine (20 to 30

mg t.i.d.), barium chloride (0.3 to 0.6 gm t.i.d.), or adrenalin (1 cc of 1:1000) may be tried. Digitalis does not appear to be contraindicated either in incomplete heart block such as occurs in active rheumatic infection, or in complete heart block, if heart failure requires its use.

In those cases of supraventricular paroxysmal tachycardia in which mechohyl is used (10–25 mg subcutaneously), it is good practice to have the patient connected to the galvanometer, if possible, while the drug is being injected. At any rate, auscultation over the heart should be made continuously. It is perhaps needless to say that atropine should be ready at hand to use if required and that mechohyl should not be used when there is an allergic history.

The electrocardiographic technic is of help in the diagnosis of the *carotid sinus syndrome*. It is our custom to take electrocardiograms during pressures over the right and left carotid sinus when their hypersensitivity is suspected, in order to record the prevailing rhythm. In the vagal type there may occur varying degree of auriculoventricular

Fig 99—In this figure is shown Lead II of the electrocardiogram taken during pressure over a hypersensitive left carotid sinus. Arrows indicate the beginning and end of pressure. There was complete cardiac standstill for 7.4 seconds, during which the patient experienced loss of vision and "black film over the eyes." Blood pressure could not be obtained during asystole.

heart block, or sinus arrest with asystole (Fig 99), during which there is fall in blood pressure and syncope.⁹

From what has been said, the importance of making the exact diagnosis, particularly of the paroxysmal rapid and slow rhythms, is apparent, not only because of the discomfort attendant upon these rhythms but also because congestive heart failure may ensue if the rhythm is not terminated, and, moreover, if the appropriate drug is not used, harm may result. The decreased functional capabilities of the heart during certain rapid rhythms indicate the need for prompt therapy (Fig 100).¹⁰

In serial electrocardiograms alterations of the T waves have been recorded with restoration of the normal rhythm after paroxysmal tachycardia.^{11, 12, 13} If changes are marked and undergo slow regression it appears that myocardial damage must have occurred associated with myocardial ischemia due to the decreased coronary blood supply which no doubt prevailed while the abnormal rhythm was present. It is known that marked decrease in cardiac output is present during paroxysmal tachycardia (Fig 100).¹⁰ Adequate rest should be insti-

tuted in such cases, although the implications and prognosis are quite different from changes occurring with closure of a coronary vessel. When electrocardiographic changes are recorded after paroxysmal

Fig 100.—In this figure is shown the effect of paroxysmal tachycardia on the cardiac output, cardiac size, circulation time and venous pressure, namely decrease in cardiac output, dilatation of the heart, and prolongation of the circulation time (Stewart, H J, Detrick, J E., Crane, N F and Thompson, W P J Clin Investigation, Vol 17)

tachycardia it is important moreover to consider whether the paroxysm might itself have been precipitated by coronary obstruction.

It is, therefore, in the diagnosis of the rhythms of the heart that the electrocardiographic technic finds one of its widest applications.

STRUCTURE OF THE HEART

The next use to which the electrocardiogram may be directed is to give information about the structure of the heart.

1 From the electrocardiogram inference may be made about preponderance of one side or the other of the heart, that is to say hypertrophy. *Right axis deviation* is commonly associated with hypertrophy of the right side of the heart, such as results from the following valvular lesions: mitral stenosis (Fig 101, C), pulmonary stenosis, tricuspid disease, or from so-called pulmonary heart disease or chronic cor pulmonale: chronic asthma, bronchitis, emphysema, pulmonary fibrosis

Fig 101—In A is shown a normal electrocardiogram, in B left axis deviation associated with aortic insufficiency of syphilitic etiology and in C right axis deviation associated with mitral stenosis.

and pulmonary arteriosclerosis (Ayerza's disease). In these the P waves may be increased in amplitude. *Left axis deviation* is commonly associated with hypertrophy of the left ventricle, such as occurs in aortic insufficiency (Fig 101, B), aortic stenosis, mitral insufficiency and hypertension.

In left axis deviation R-T₁ and perhaps R-T₂ may be depressed and T₁ negative and coved, and possibly T₂ negative and coved. On the other hand, in right axis deviation there may occur depression of R-T₃ and perhaps of R-T₂ together with negativity and coving of T₃ and perhaps of T₂.

2 *Congenital malformations* of the heart may give rise to electro-

cardiographic changes to deviation of the electrical axis, or defects in QRS or P-R conduction¹⁴ For instance, right axis deviation is found in pulmonary stenosis left axis deviation in coarctation of the aorta Uncomplicated patent ductus arteriosus gives rise to no deviation of the electrical axis

3 The electrocardiogram reveals data about structural damage to the heart

(a) In the first place, the electrocardiogram gives information about the conducting system from the auricles to the ventricles, in

Fig 102 —A series of electrocardiograms of a patient during an attack of acute rheumatic fever with active carditis, shown in order to illustrate the range of conduction defects that may be encountered There is gradual increase in P-R conduction time in A and B and C, P and T are superimposed In D there is an occasional blocked P wave in Leads I and II, and 2:1 block in Lead III In E complete heart block prevails

that any degree of block may be revealed from prolonged P-R to complete heart block Alterations in the conducting system may be occasioned by (1) structural damage, such as occurs in active rheumatic infection (Fig 102), attributed also to vagal effects, in diphtheria, in gumma involving the bundle, in arteriosclerotic lesions, and in congenital defects especially when the interventricular septum is patent, (2) functional or nutritional alterations, (3) toxic effects of drugs, such as digitalis and (4) vagal effects The electrocardiogram is often

a valuable adjunct in ascertaining the activity of rheumatic infection, namely by prolongation of P-R conduction (Fig 102) and by irregularities, as well as about damage occurring in the course of diphtheria

(b) *Bundle branch block* can be diagnosed only with reliability in electrocardiograms although splitting of sounds at the apex and a bifid apex beat have been described in this lesion. The grave prognostic implications of bundle branch block are adequate reason for knowing about its presence because the duration of life is shorter in those who exhibit this defect. Bundle branch block is most commonly associated with arteriosclerotic heart disease but is occasionally a congenital

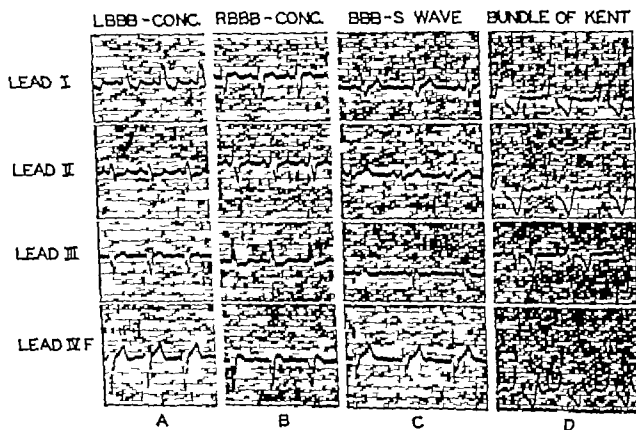

Fig 103—Electrocardiograms illustrating types of *bundle branch block* A shows left bundle branch block of concordant type, B right bundle branch block of concordant type, and C bundle branch block wide S wave type. In D is recorded an example of the so-called short P-R—long QRS, or Wolff Parkinson White or bundle of Kent syndrome.

manifestation. Electrocardiographically, bundle branch blocks can be divided into right and left varieties, each having concordant and discordant types, and the S wave type (Fig 103, A, B, C). From statistical analysis, the concordant types are associated with the shortest life span, the S wave type with the longest life span almost approaching the normal, and the discordant types with a life span intermediate between these other two.¹⁵ On the other hand, bundle branch block may be transient in active rheumatic infection, or it may be functional manifestation in uremia¹⁶ and in arteriosclerotic heart disease.

The so-called short P-R—long QRS (Fig 103 D), Wolff-Parkinson-

White or bundle of Kent syndrome is a congenital defect and patients exhibiting it are prone to attacks of paroxysmal tachycardia.^{17, 18} They may have other congenital cardiac defects. The prognostic implications of this group are sufficiently different from other types of bundle branch block to warrant recognition.

(c) The situation in which the electrocardiogram yields much information is in *coronary thrombosis* or myocardial infarction. It has only been a matter of twenty-five years since Dr. Herrick,¹⁹ the dean of American Medicine, first described the clinical manifestations of acute coronary occlusion, and now it is a diagnosis that third-year clinical clerks can make with a reasonable degree of accuracy. It is one of the surprising events of medicine that a diagnostic entity which has been recognized scarcely twenty-five years has now come to be one of the major causes of concern and alarm for those turning 40. From the number of electrocardiographic papers dealing with the changes in this disease, one is likely to get an exaggerated sense of the value of the technic in this situation. The electrocardiogram yields, in most instances, additional evidence that acute coronary occlusion has occurred, and may give the site of location—the so-called T_1 and T_3 types indicating anterior apex, and posterior base locations respectively. The introduction of the chest derivations was an additional refinement in the electrocardiographic knowledge of this accident. But with the good a certain amount of evil arose due to the rapid appearance of so many chest derivations and to the difficulties inherent in standardization. The standardization of chest leads by the American Heart Association is to be commended,²⁰ for out of it comes some degree of uniformity. Several chest leads may be taken when there is indication or when the IVF derivation fails to give the expected information. Chest leads should be given a balanced place in the electrocardiographic technic.

From electrocardiograms inference can frequently be made about the extent of myocardial infarction, the part of the heart involved, conduction defects, intraventricular heart block, and about the recovery process, or more properly the evolution of changes. In this connection it is of use in therapy since it is the accepted practice to keep a patient who has suffered coronary occlusion at rest in bed until the electrocardiogram has ceased to undergo marked changes, and has become more or less stabilized, even though this period is beyond the four to eight weeks that a patient suffering acute coronary occlusion without complications is usually immobilized. In making this statement, it is realized that in some instances the electrocardiogram returns slowly to normal during a period of twelve to eighteen months. In typical cases it is now possible to distinguish certain patterns which enables the localization of the infarction, namely whether anterior apex, posterior base, or lateral. The anterior apex (anterior descending branch of left coronary artery) type is characterized early by elevation of

R-T₁ and maybe R-T₂, depression of R-T₃ and elevation of R-T₄, Q₁ and Q₄ may be present. In the evolution of the electrocardiogram now taken serially or day by day, there occurs a gradual transition to

Fig 104—Serial electrocardiograms derived from a patient who had suffered myocardial infarction at the anterior apex region of the heart, illustrating the evolution of the changes, on the dates given.

negative T₁, maybe negative T₂, and positive T₃, and negative T₄, the so-called T₁ type of electrocardiogram (Fig 104)

The posterior base type (right coronary) is characterized by more or less opposite signs from the anterior apex type, namely early de-

Fig 105—Serial electrocardiograms derived from a patient who had suffered myocardial infarction at the posterior base region of the heart, illustrating the evolution of the changes on the dates given. Normal rhythm was present on October 17 1938 and November 9 1938 while auricular fibrillation was present on October 21 1938

pression of R-T₁ and elevation of R-T₂ and R-T₃ and no change in R-T₄ or slight depression. As the evolution occurs there is a gradual transition to positive T₁ and negative T₂ and negative T₃ with up-right T₄ and return of R-T₄ to the isoelectric level if earlier it

been displaced downward. There may be a deep Q_3 . This is the so-called T_3 type (Fig 105). The typical form of the T waves when negative or diphasic is described as being "coved."²¹

In Figure 106 are shown the records of a patient who had electrocardiographic evidence of anterior apex lesion and one year later evidence of posterior base lesion. He died shortly after this last accident. At autopsy, the scar of the first myocardial infarction was seen involving the apex and the septum, (anterior apex) and the fresh infarction involving the posterior and base.

And finally, a lateral type (circumflex branch of left coronary artery) has been described, characterized by depression of R-ST in I and II and IVF. T_3 is normal.²² The chest lead is similar to posterior

Fig 106—Electrocardiograms derived from a patient who suffered myocardial infarction first in the posterior base region of the heart, July 30, 1938 to August 18, 1938, and later, January 19, 1939, in the anterior apex region. The patient died during this last episode and autopsy revealed the old scar of the earlier posterior base infarction, and the recent infarction at the apex of the heart anteriorly.

base infarction but the three standard leads are different. There is rapid return of the electrocardiogram to normal form, so that the electrocardiographic deformity may escape record. Auricular fibrillation occurs frequently in these cases. Certain data support the definition of this electrocardiographic pattern while other studies fail to support the recognition of a typical electrocardiogram.²⁴

Large negative T_4 (15 mm) indicates that anterior apex lesion may have occurred at some time in the past and large positive T_4 that a posterior base lesion may have occurred (Fig 107).

The distortion of the electrocardiogram by bundle branch block may cloud the electrocardiographic diagnosis and localization of infarction. The chance occurrence of a ventricular premature contraction may yield the typical contour to be expected.

It may be of help in prognosis to localize the infarction since it appears that the lateral ones have the least grave prognosis, the posterior base next and the anterior apex the most serious import.²⁵

The clinical story and course pointing to acute coronary occlusion should outweigh negative electrocardiograms, even though electrocardiograms derived serially show either minor changes or none at all as occasionally is the case.

If it is possible to make them, serial electrocardiograms at few-day intervals may record changes which a single electrocardiogram may have left undetected. Serial electrocardiograms also give a record of

Fig 107-4 shows an instance of marked increase in amplitude of T₄ and in B, an increase in negativity of T₄

the evolution of changes and may be the basis for deciding upon therapy and the patient's activity

It must be kept in mind that occasionally closure of a coronary vessel may be due to coronary embolism, especially in patients suffering from subacute bacterial endocarditis. The symptoms and course and electrocardiographic patterns are, of course, similar to those resulting from coronary thrombosis.²⁰

(d) The situation in which we would like more help from the electrocardiogram is in *coronary artery disease with coronary insufficiency*, whether the result of earlier occlusion with restoration of the

electrocardiogram to a normal configuration or the result of widespread coronary sclerosis. Certain forms of the electrocardiogram are recognized that are attributed to coronary artery changes, but it is the borderline case which lacks definiteness (see p 615)

(e) There are certain forms of the electrocardiogram with low amplitude of all complexes and splitting of the QRS waves that are attributed to myocardial disease, implying that chronic changes have occurred in the heart muscle—*fibrosis*, perhaps secondary to general decrease in blood supply, which interferes with the spread of the excitation wave through the muscle mass. They have a different contour from the large complexes and the T waves of those attributed to coronary artery disease, such as one finds in young individuals with *arteriosclerosis*, resulting from hypertension, for instance. This inference should only be made when the clinical history and age of the patient are taken into account.

(f) The electrocardiogram may undergo alterations in *trauma* such as a blow to the front of the chest, contusion, crush injury, steering wheel injury²⁷ similar to those seen in myocardial infarction with or without coronary closure. Partial heart block, sinus bradycardia, splitting of the QRS complexes, increase in amplitude of the T waves, and changes in form of the T waves going on to coving have been reported.²⁸ In stab and shotgun wounds damaging the heart, electrocardiographic changes occur. When there is ample time for operation in order to suture the heart muscle, or to ligate a severed coronary vessel, the subsequent electrocardiographic alterations correspond to those expected from the anatomical location involved,^{29, 30, 31, 32} and resemble those seen in myocardial infarction. The changes may be modified by the presence of pericarditis.²⁹

(g) The invasion of the heart by *primary tumors* or by *metastases* from remote or contiguous tumors may give rise to changes in the electrocardiogram.³³ In Boeck's sarcoid, abnormalities of the T waves may be found when the myocardium and pericardium are involved.³⁴ In leukemia there may be infiltration of the heart muscle giving rise to alteration of the T waves and conduction defects.³⁵ Xanthomatosis may be the cause of electrocardiographic changes.

(h) During *pericardial resection* in the treatment of chronic constrictive pericarditis irregularities of rhythm may occur probably in part due to mechanical stimulation of the muscle, in part to trauma to the muscle, and in part to torsion of the heart during the dissection. If auricular fibrillation prevails, ventricular premature contractions and transient ventricular paroxysmal tachycardia may occur. In the presence of normal rhythm auricular premature contractions, transient auricular fibrillation, auricular flutter and auricular paroxysmal tachycardia may be recorded.³⁶ T wave changes may continue to occur for many months afterward.

THE ELECTROCARDIOGRAM IN DISEASE

1 The electrocardiogram in *vitamin B deficiency* may show tachycardia, low voltage of the T waves, and low amplitude of QRS complexes (Fig 108) Nicotinic acid deficiency may be associated with negativity of the T waves of the electrocardiogram, the T waves become more normal after giving nicotinic acid³⁷

2 The electrocardiogram has been found to undergo changes in *acute pericarditis*, whether due to rheumatic fever, tuberculosis, uremia, myocardial infarction, pneumonia, or to unknown etiology Many of these changes are similar to those seen in acute coronary occlusion, but an attempt has been made to make electrocardiographic distinc-

JULY 11, 1938

AUG 3, 1938

LEAD I

LEAD II

LEAD III

Fig 108—Two electrocardiograms of a patient who was thought to have beri beri heart disease.

tions In typical cases there is elevation of R-T segments in all three standard leads, as well as *elevation of R-T₄ without Q₄ appearing* (Fig 109) There is absence of the usual T₁ and T₃ pattern and also in the absence of the well developed Q pattern pericarditis differs from myocardial infarction. Clinically there are only few occasions in which acute pericarditis is confused with coronary occlusion even when the latter is associated with pericarditis.³⁸

Recent papers have reported the occurrence of pericarditis with electrocardiographic changes during the course of primary atypical pneumonia and virus pneumonia.^{39 40} The changes occurring during pericarditis⁴¹

3 The electrocardiogram in *chronic constrictive pericarditis* (Pick's disease) has been found to have surprising uniformity low amplitude of QRS and T waves throughout and perhaps coving of T_1 and T_2

Fig 109—Serial electrocardiograms derived from a patient who had acute pericarditis of rheumatic etiology, illustrating the changes commonly observed

are common (Fig 110)⁴² After operation, even though cure takes place, there may be surprisingly little regression of the electrocardiogram

Fig 110—Electrocardiograms derived from a patient suffering from chronic constrictive pericarditis, illustrating the typical findings In A the patient was lying on his back, in B, on his right side, and in C, on his left side, in order to detect shifting of the electrical axis of the heart with change in position of the body The electrocardiogram is essentially unchanged by this procedure

4 There is another lesion which has been found to give rise to profound electrocardiographic changes which may be confused with those occurring in acute coronary occlusion, especially since its clinical

symptomatology may simulate acute coronary occlusion at times namely, *pulmonary infarction* My attention was first directed to this several years ago by the case of a woman, aged 42 years, who experienced symptoms pointing to acute coronary occlusion, pain, fall in blood pressure, rise in temperature. The electrocardiogram showed changes which were interpreted as due to acute coronary occlusion. When the patient died, a large pulmonary infarct due to a large thrombus, which had extended up from the right heart, was found at autopsy. This case made a profound impression on me and I kept on the alert for other cases—known pulmonary infarcts and electrocardiographic changes. In the meanwhile, McGinn and White⁴³ had come upon the same phenomenon and reported their cases under the title of 'acute cor pulmonale'. The electrocardiographic characteristics appear early to be staircase deformity of T_1 and T_2 , later low flat or

Fig 111—Electrocardiograms derived serially from a patient who had pulmonary infarction to illustrate the common changes.

inverted T_2 and negative T_3 and early, deep S wave in Lead I which may be split. T_4 is negative and QRS complexes normal. T_4 becomes upright with improvement (Fig 111).⁴⁴ It is similar to the T_3 or posterior type of myocardial infarction. The alterations in the electrocardiograms occur in rapid succession so that the usual form of the electrocardiogram is restored earlier than in most instances of coronary occlusion. The electrocardiographic changes in pulmonary infarction are probably due to change in pressure in the pulmonary vessels. Certain experimental data dealing with this have been reported.⁴⁵ Overloading the circulation with fluids intravenously induces changes in the T waves and R-T segments somewhat like those in pulmonary infarction.

5 The electrocardiographic changes in *dissecting aneurysm* of the aorta or *rupture of the aorta* in coarctation of the aorta for example

may simulate those seen in coronary occlusion (Fig 112) This accident, however, is usually not associated with fall in blood pressure

It appears that in acute coronary occlusion, pulmonary infarction, acute pericarditis, rupture of aorta, the changes when slight may be similar and confusing, and it is likely to be just the case that the extra evidence is needed The configuration resulting from digitalis will be described later

6 Certain changes in the electrocardiograms are said to occur in *gallbladder diseases*,⁴⁶ and regress with removal of gallstones Since gallbladder disease occurs most commonly in the same age group as coronary artery disease, the separation of the two effects has not yet been clearly defined

7 The electrocardiogram may be turned to account in the following situation The patient has typical signs of aortic stenosis, and aortic insufficiency of rheumatic etiology There are also signs of mitral stenosis and mitral insufficiency but the question arises as to whether *mitral stenosis* is present or whether it is an *Austin Flint murmur* If there is marked aortic stenosis and aortic insufficiency, left axis deviation

Fig 112—Serial changes in the electrocardiograms in a patient with coarctation of the aorta in whom rupture of the aorta occurred

tion is commonly present and may overbalance the right axis deviation which may have been expected in cases of mitral stenosis In cases of aortic stenosis and aortic insufficiency together with mitral stenosis, there may, however, be *no* deviation of the electrical axis (Fig 113) On the other hand, if right axis deviation had been present with the diagnosis of aortic stenosis and aortic insufficiency, that also would have been evidence of the presence of mitral stenosis

8 In a patient who is suspected of having *Fiedler's acute isolated myocarditis* the presence of bundle branch block and low amplitude of the QRS complexes may be additional evidence of the grave myocardial damage which this disease causes

9 In the course of *acute glomerulonephritis* in children⁴⁷ after earlier depression of R-T_{1 2} especially, there may be flattening or inversion of T waves in one or more leads, in T₃ as often as in T₁ Heart failure was more common in those with T₁ inversion

10 Most patients with *cardiovascular syphilis* have abnormal electrocardiograms Left axis deviation occurs when aortic insufficiency is present. There may be anterior apex pattern of the electrocardiogram

due to involvement of the coronary ostia Auriculoventricular as well as bundle branch block have been recorded⁴⁸

11 Electrocardiographic changes have been described in *Friedreich's disease* conduction defects including complete heart block with Stokes-Adams syndrome are common Bundle branch block and T wave abnormalities have also been described⁴⁹

12 In *trichinosis* there may be clinical and electrocardiographic evidence of myocardial involvement The cardiac manifestations are said to be due to active migration of the larvae to the myocardium and not to a toxic substance. The electrocardiographic changes are in the T

Fig 113—Electrocardiogram from a patient who had mitral stenosis and in sufficiency and aortic insufficiency illustrating the absence of deviation of the electrical axis.

waves with the development of negativity of T_2 and T_3 and alteration of T_4 ^{50 51} From the nature of the myocardial lesions a characteristic electrocardiogram is hardly to be expected

13 Transient alterations of the T waves of the electrocardiogram have been reported in *acute pancreatitis*⁵² Depression of the R-T segments which might be confused with infarction of the lateral wall of the left ventricle have been described in *perforation of a gastric ulcer*⁵³

14 Transient changes have been recorded in the T waves of the electrocardiogram as well as prolongation of the P-R time during the course of *epidemic parotitis*⁵⁴

15 Electrocardiographic alterations have been recorded during *epileptic seizures*, and T waves may decrease in amplitude⁵⁵ or increase in amplitude Metrazol convulsions result in increase in amplitude of the T waves and many types of irregularities of the heart rhythm, namely both auricular and ventricular premature contractions, nodal rhythm, increase in P-R conduction, going on to incomplete and complete heart block⁵⁶ Electrical convulsions may give rise to essentially similar changes, namely increase in amplitude of the T waves, both auricular and ventricular premature contractions, and nodal rhythm⁵⁷

16 Nonspecific transient changes in the T waves have been described in *scarlet fever* but rarely conduction defects^{58 59} Transient alterations of the T waves may be recorded in *acute tonsillitis*

17 Changes in the T waves may be observed in any of the acute infections such as *acute osteomyelitis with bacteremia* Changes in rhythm and T waves have been described in *spirochetel jaundice*⁶⁰

18 The following alterations have been recorded during and following *diabetic coma*⁶¹ lengthening of the Q-T interval, depression of the R-T interval and inversion of the T waves The most marked changes occurred not during coma but twenty-four hours later when the patients had improved

19 In *chronic and severe anemia* T waves may be flattened, and less frequently, depression of R-T segments and low voltage of the QRS complexes⁶² On the other hand, there may be no marked alterations in pernicious anemia⁶³

ELECTROCARDIOGRAM AND POSITION OF THE HEART

The electrocardiogram can be used to give information about the position of the heart, and conversely, the position of the heart has to be taken into account in reading the electrocardiograms

1 The *body build* of the subject alters the electrocardiograms Short, stout subjects tend to induce left axis deviation, and the long, narrow type to give rise to right axis deviation

2 The form of the electrocardiogram in *dextrocardia* may be placed under this rubric, the physical examination of the subject should reveal this deviation from the usual and confirmation secured by fluoroscopy and x-ray examination (Fig 114, A) In the electrocardiogram Lead I appears to be upside down, and Leads II and III to be interchanged (Fig 114, B)

3 *Pneumothorax, collapse of lung, large pleural effusion and chest deformity* alter the electrocardiogram by shifting the heart *Pregnancy and ascites* by raising the diaphragm tend to give left axis deviation In pregnancy Q₃ may develop together with a negative T wave in Lead III⁶⁴

4 *Interstitial emphysema* which may be confused clinically with *acute coronary occlusion*⁶⁵ In them electrocardiographic changes do

not occur. Interstitial emphysema occurs usually in younger individuals than does coronary occlusion.

5 In *chronic constrictive pericarditis*, the fixation of the heart in the electrocardiogram⁴⁵ combined with fixation of the point of maximal impulse clinically and fluoroscopically is additional evidence in

Fig 114—A A 2 meter x ray photograph of the chest showing the position of the heart B, the electrocardiogram derived from this patient with dextrocardia.

summing up the evidence for Pick's disease. It is recalled that large hearts may not shift, but the constricted hearts are usually not much enlarged thereby giving more weight to this sign. The fixation of the electrical axis, even though the position of the body is changed is shown in Figure 110

PHARMACOLOGICAL AND THERAPEUTIC USES

So much for information about structure. To what pharmacologic uses and the management of what drugs in the course of therapy may the electrocardiogram be directed?

1 It is fitting that *digitalis* should be mentioned first. Cohn and Jamieson⁴⁶ first studied the changes induced in the electrocardiogram by *digitalis*. This has been frequently confirmed.⁴⁷ The changes occur in the T waves and R-T segments in any of the three leads the T waves may become lower in amplitude, or go on to negativity, or if

negative they may become upright (Figs 115 and 116) Prolonged P-R conduction and heart block may occur if toxic amounts have been given

(a) Changes in the T waves and R-T segments are not an indication of the degree of digitalization for they may occur with amounts

Fig 115—Electrocardiograms showing the effects of digitalis on the four leads of the electrocardiogram when there is regular sinus rhythm showing alterations in T waves, R-T segments, and heart rate. Electrocardiogram A was taken before, B, twenty-four hours after 17 gm of digitalis by mouth in twenty-four hours, and C, two days later. In the chest leads in the first column designated IVF the chest electrode was placed at the apex and in those in the second column designated IVF it was placed about 1 cm beyond the apex. In this instance there was no marked difference (Stewart, H J and Watson, R F. *Am Heart J.*, Vol 15.)

short of therapeutic ones.⁶⁸ Digitalis given by mouth may give electrocardiographic changes in one to two hours, and in slightly shorter time when given by rectum, and in shorter time still when given intravenously.

Fig 116—Electrocardiograms showing the effect of digitalis on the four leads of the electrocardiogram when there is auricular fibrillation. A served as a control. The patient was given 1.8 gm digitalis by mouth on November 2, 1943. B, taken on November 3, 1943, shows increased negativity and change in form of the T waves in Leads I and II, with change in form of the T waves in Leads III and IVF.

(b) In patients with normal sinus rhythm—when digitalis is used, an occasional electrocardiogram may prevent overdigitalization if changes in P-R time are detected. Therapeutic amounts of digitalis do not usually cause conduction defects (Fig 115).

(c) Ventricular premature contractions clinically and in the electrocardiogram may indicate overdigitalization.

(d) The electrocardiographic changes in the chest lead occurring with digitalis may simulate those attributed to coronary occlusion and for this reason the question of the use of digitalis must be taken into account in reading electrocardiograms (Figs 115 and 116).⁶⁷

(e) With great rarity transient bundle branch block has been observed following overdigitalization.

(f) Calcium and digitalis have somewhat similar effects on heart muscle and should not be given simultaneously.⁶⁸ Ventricular premature contractions appear with smaller amounts of digitalis when calcium is given intravenously,⁷⁰ and deaths have been reported following the use of calcium salts intravenously in digitalized patients.⁷¹ The results of experiments in animals with normal heart muscle may not be applicable to instances of heart disease in the clinic.⁷²

2 In long-continued use of *quinidine* in the treatment of ventricular premature contractions and recurrent ventricular paroxysmal

Fig 117—Series of electrocardiograms derived from a patient suffering from spontaneous myxedema, illustrating the low amplitude of the QRS complexes, and the conduction defect followed by repression of changes when the patient was given thyroid extract. (Stewart H J, Destrack J E and Crane, N F J Clin. Investigation, Vol. 17)

tachycardia, as well as in the use of larger amounts to terminate abnormal rhythms, the prolongation of the QRS time may be an early toxic sign. Recent studies⁷³ have shown that *atabrine* and *quinine* decrease the amplitude of the T waves and *plasmaquin* increases the amplitude of the T waves above normal.

3 In a typical case of myxedema the R and T waves are of low voltage and the P-R time prolonged (Fig 115, Jan 30, 1936). With the administration of *thyroid extract* the P-R time decreases and the amplitude of the T waves and R waves increases (Figs 117, March 5 and April 8 1936). The reaction is a reversible one.⁷⁴ It is important to watch therapy carefully if patients are in the coronary age group because coronary occlusion may occur while under therapy. On the other hand the electrocardiographic picture in *hyperthyroidism* is not diagnostic or characteristic at times the T waves being tall and pointed and at other times tall and rounded.⁷⁵

4 *Nicotine* will be mentioned briefly. There is no uniformity of opinion about the effect of tobacco on the heart.⁷⁶ Nevertheless, in certain patients smoking may be associated with pain, palpitation, or

Fig 118—Effects of smoking cigarettes in a patient who experienced irregularity of the heart and precordial distress on smoking. After the control (A) was taken the patient smoked for ten minutes. Frequent electrocardiograms were taken. B was taken eight minutes, and C twenty minutes after he stopped smoking. The time marker was not running while C was taken.

Fig 119—An electrocardiogram showing prolongation of the Q-T interval associated with chronic nephritis with uremia.

irregularity of the heart. Records are reproduced of a patient, aged 20 years, in whom smoking gave rise to changes in the form of the T waves and R-T segments, especially T₂, tachycardia ventricular pre-

mature contractions (Fig 118) and to precordial distress. The most consistent effect on the electrocardiogram after smoking has been found to be decrease in amplitude of the T waves.^{77 78}

5 At times, *hypocalcemia* may be hypothecated from the electrocardiogram when the Q-T interval is prolonged⁷⁹ when it has not been suspected clinically (Fig 119). The Q-T prolongation may occur in patients with chronic gastrointestinal lesions, chronic nephritis, or hypoparathyroidism.

6 The use of *potassium salts* may give marked changes in the electrocardiogram and lead to abnormalities of conduction, abnormal rhythms and cardiac standstill by depression of the activity of the sinus node (Fig 120).^{80 81 82}

Fig 120—A series of electrocardiograms derived from a patient who was given potassium iodide. A was taken after digitalization and B while the patient was on maintenance amounts of digitalis, during which time the electrocardiogram remained constant; these two records served as controls. C and D show the changes induced by potassium iodide and E shows reversion of the electrocardiogram to its control forms, A and B, after potassium iodide was discontinued (Stewart, H J and Smith, J J. Am J M. Sc., Vol 201)

7 On the other hand abnormalities of the electrocardiogram—QRS conduction and T waves—have been recorded in familial periodic paralysis, which are reversed by the administration of potassium salts (Fig 121).⁸³

8 *Acute blood loss* may lower the T waves, even to their becoming isoelectric or negative. Depression of the R-T segments and lowering of the amplitude of the QRS complexes may result. The changes persist for two to nine days.^{84 85} The alterations may be due to lesions in the myocardium caused by insufficient blood supply.

9 Sympathetic stimulation occasioned by *exercise* or *fear* or *adrenaline*⁸⁶ and vagal inhibition resulting from *atropine* lowers the T waves in Lead II even to the point of inversion. On the other hand, vagal

stimulation caused by *ergotamine tartrate* and after exercise raises the T waves

10 In patients suffering from angina who have abnormal electrocardiograms, *nitroglycerin* restores the electrocardiogram to a more normal form⁸⁷ (see p 615)

11 *Nicotinic acid* in large amounts (300 mg) which induces flushing has been found to prevent the occurrence of angina pectoris resulting from exercise and also to restore the deformity of the T waves and R-T segments of the electrocardiogram caused by exercise to a more normal contour, presumably by dilatation of the coronary vessels sharing in the generalized vasodilatation⁸⁸ (see anoxemia test, p 616)

12 Mention (p 593) has already been made of the use of *mecholy* in the treatment of supraventricular paroxysmal tachycardia Mecholy!

Fig 121—Changes apparent in the electrocardiogram in *familial periodic paralysis* A, taken when the patient was feeling well, serves as a control B was taken during an attack of paralysis, following which 42 gm of potassium chloride was given by mouth C was taken after the attack had terminated as the consequence of giving potassium chloride Serial electrocardiograms which were taken after ingestion of potassium chloride showed the gradual regression of the electrocardiograms' defects (Stewart, H J., Smith, J J and Milhorat, A T Am. J Med Sc., Vol 199)

may induce any grade of heart block, from prolongation of the conduction time to incomplete heart block and complete heart block⁸⁹ through its parasympathetic effects Atropine abolishes these effects

13 During *surgical anesthesia* variations in amplitude of the QRS complexes and T waves, shifting of the R-T segment and changes in P-R interval occur frequently Arrhythmias are more common in abnormal hearts than in normal ones Premature contractions, complete heart block, paroxysmal auricular fibrillation and irregularity of the ventricles have been recorded Changes may persist for many hours following anesthesia The highest incidence of irregularities occurred in chloroform anesthesia There is apparently no correlation between the occurrence of abnormalities and the depth of anesthesia or the surgical procedure⁹⁰

USE OF ELECTROCARDIOGRAM IN FUNCTIONAL TESTS

And finally, can the electrocardiogram be used to give information about function? Sporadic attempts have been made to turn this technic to account in estimating the functional capacity of the heart but it has remained for Levy to pursue it systematically.

Many patients in whom the differential diagnosis of angina pectoris arises present electrocardiograms which are essentially normal and it was to the elucidation of the objective diagnosis of coronary insufficiency that Levy directed the use of electrocardiograms.

1 It has long been known that the electrocardiogram may undergo changes in the T waves and R-T segments during an attack of angina pectoris only to assume its usual form with the passing of the attack. When changes occur it is useful in the differential diagnosis of angina

Fig 122—Electrocardiograms illustrating the effects of exercise in a patient suffering from angina pectoris. After resting one-half hour the control electrocardiogram (A) was taken B was taken after the patient had walked over three steps for fifty times with the induction of precordial pain and shows depression of the R-T segments in Leads I, II and IV F C was taken after resting and shows restoration of the electrocardiogram to its control form.

2 In patients who experience precordial distress, it is important to decide whether the pain is associated with cardiac disease and whether it is angina pectoris. Since typical angina is associated with effort, the effect of exercise on electrocardiograms has been studied together with a correlation of the occurrence of pain. By inference appropriate electrocardiographic changes are interpreted as evidence of impairment of the coronary circulation. In certain patients with coronary artery disease marked alterations of the T waves and R-T segments occur during exercise, going on to negativity and depression of these components respectively changes which disappear shortly after resting (Fig 122).

In spontaneous angina and that resulting from the exercise test, the electrocardiographic changes are attributed to transient alterations in the myocardium because of inadequacy of the coronary circulation in short to anoxemia of the heart muscle or to the accumulation of metabolites.

3 Levy has studied patients exhibiting angina pectoris during the anoxemia induced by breathing a mixture of 10 per cent oxygen and 90 per cent nitrogen and found that in certain ones pain occurred and in others it did not. In short, pain being subjective was not a dependable sign, as a consequence he sought for objective data which the use of electrocardiograms supplied. He devised an *anoxemia test* using electrocardiographic changes as the objective record.⁹¹ He has defined the changes in the T waves and R-T segments of the three standard leads and chest lead that may be expected in normal individuals when subjected to the test and contrasted them with those occurring in patients exhibiting coronary artery disease.

The test is said to be "positive when anyone of the following is found (1) the arithmetic sum of the R-ST deviations in all four leads (I, II, III and IVF) totals 3 mm or more (2) There is partial or com

Fig 123—Electrocardiograms in an anoxemia test exhibiting "positive" changes in a patient suffering from angina pectoris. *A* was the control record. *B* was taken after breathing 10 per cent oxygen and 90 per cent nitrogen for twenty minutes. *C* was taken twenty minutes after breathing room air. Attention is directed to occurrence of negativity of the T waves in Leads I, II, III and IVF, while breathing the low oxygen, and reversion to the control form after breathing room air.

plete reversal of the direction of the T waves in Lead I, accompanied by an R-ST deviation of 1 mm, or more, in this lead (3) There is complete reversal of the direction of the T wave in Lead IVF, regardless of any associated R-ST deviation in this lead."⁹¹

This test gives promise of giving valuable additional information when the symptoms are not typical or not clearly defined and may be helpful in separating malingerers from those suffering true angina pectoris.

The exercise test is positive at times when the anoxemia test is negative, and at other times is negative when the anoxemia test is positive or both may give positive tests.⁹²

In Figure 123 are reproduced the electrocardiograms in a so-called positive anoxemia test in which breathing the 10 per cent oxygen 90 per cent nitrogen mixture was associated with marked negativity of

T₁ 2 3 4 with depression of R-T₁ 2 3 4 and also subjectively with pain, both of which were promptly dissipated by breathing room air for ten minutes

4 Occasionally the symptoms associated with hiatus hernia may be confused with those of angina^{83 84} In *hiatus hernia* electrocardiographic changes do not occur unless the patient also has coronary artery disease. The anoxemia test may be used in the differential diagnosis of these two entities

5 Occasionally *pulsus alternans* which is evidence of grave myocardial weakness is associated also with electrical alternans in the electrocardiogram (Fig 124)

Fig 124—Electrocardiograms illustrating electrical alternans in a patient suffering from severe myocardial disease due to arteriosclerosis. "X" indicates the taller QRS complexes and "Y" the lower ones.

FUNCTIONAL DISEASES

The electrocardiogram has been more useful in its contributions to organic heart disease than in so-called functional heart disease, except by its negative evidence. For instance, in *neurocirculatory asthema* there may be transient changes in the T waves. T₂ may be flattened or even inverted⁸⁵ probably due to preponderant sympathetic nerve imbalance. T₂ may become upright with improvement.

Marked electrocardiographic changes may be induced by fear. When there is increase in amplitude of the P and T waves, it has been attributed to sympathetic stimulus of the contractions of the heart.

There may be more marked changes amplitude of the QRS complexes may decrease, T wave deflections may become negative, and R-T segments descend below the the isoelectric level and become deformed, changes which have been attributed to coronary constriction caused by vagal stimulation⁹⁶

There may be disturbing symptoms brought about by *hyperventilation*^{97 98} There may be flattening of the T waves with hysterical overventilation and tetany, just as *alkalosis* from voluntary overventilation or from ingestion of sodium bicarbonate reduces the amplitude of T waves On the other hand, *acidosis* produced by exercise or ingestion of ammonium chloride increases the amplitude of T waves⁹⁹

CONCLUSIONS

The general pattern of an individual's electrocardiogram with continued good health remains remarkably constant over long periods of time It appears, however, that here is a large variety of diseases, drugs, emotional states, and events (eating, drinking) in the course of the business of living which induce transient, prolonged or permanent impressions on an individual's electrocardiographic pattern The most common of these have been mentioned in order to convey an impression of wide range of the factors which have to be taken into consideration in the interpretation of electrocardiograms It should be emphasized that the clinical history and findings should be utilized in arriving at the correct interpretation for it is only in a few instances that the patterns are sufficiently characteristic to be related to their proper origin Among these few are the irregularities, typical coronary occlusion patterns, typical pulmonary infarction patterns, typical pericarditis patterns, and typical digitalis effects Moreover, instances have been related to illustrate how disease remote from the heart may alter the electrocardiogram by indirection the shock of acute peritonitis from perforation of gastric ulcer, the disturbed components of the blood and change in blood pressure in diabetic coma, etc , may be cited as examples

A word on the misuse of electrocardiograms may be in order They are now and then requested with this inquiry "Can the patient be operated upon?" It is apparent that electrocardiograms do not yield this kind of information about function A careful physical examination and history are much more important to answer that question In the formulation of the case, an electrocardiogram may contribute and yield certain information that plays its part in the intelligent evaluation of the case, but as an isolated observation it cannot make such a decision

The electrocardiogram therefore may be used to contribute information about rhythm, structure, position of heart, data which contributes to the whole clinical picture, therapy, effect of drugs, emotions, and function The electrocardiogram has made enormous contributions to

our knowledge of heart disease, and the technic can be used to contribute to the skilled diagnosis and treatment of patients, but an electrocardiogram is not necessary in the case of every patient that the physician sees or of every patient with heart disease in order to make a correct diagnosis or to carry out careful, correct treatment. If one is fully aware of its limitations there is no reason, however, for not taking electrocardiograms in any cases one wishes or making the work-up as complete as possible or using them for gaining further information, in short, as an investigative weapon. The implement is being made more and more available both as a consequence of improvement and simplification of machinery, and by the education and heart consciousness of the public, but in order to meet both forces it is necessary that the electrocardiograms be interpreted (1) by those who have had ample training (2) and by those who are interested not only in heart disease but also general medicine for the sake of a balanced and not too one-sided viewpoint and (3) finally it is necessary that an intelligent use of electrocardiograms and recognition of the situations in which help may be expected from this technic should be kept in mind.

THE DIFFERENTIAL DIAGNOSIS OF PEPTIC ULCER

I W HELD, M D *

DIFFICULTIES IN DIAGNOSIS OF INTRA-ABDOMINAL DISEASE

THE difficulty offered in the differential diagnosis of intra-abdominal diseases, particularly of the digestive tract, is too well known to warrant extensive discussion. As compared to diagnosis of diseases of any other part of the body, it more frequently involves a decision between medical or surgical treatment as the method of necessity, which is of the utmost importance to the patient as well as to the physician. Such decisions must be made not only in acute diseases of the digestive organs, but also in diseases of a chronic nature.

Gaithes¹ expressed his keen appreciation of this problem in the following manner: "Abdominal diagnosis resembles in various details its fellow science archaeology, both find their greatest triumphs in tracing hidden levels, but here they diverge. The farther the archaeologist delves, the greater his enlightenment, while the farther the abdominal diagnostician seeks and the wider and deeper his experience the more clearly he realizes how large is the number of syndromes presenting atypical, puzzling, frequently baffling symptoms."

Among the outstanding reasons for the difficulty in the diagnosis of diseases of the digestive tract is the fact that the parasympathetic and sympathetic nervous system and the autonomous innervation by the Auerbach and Meissner plexuses are intimately interwoven with the function of the digestive organs. Disturbance in the function of one organ may strongly simulate disturbed function of another organ and thus render impossible the clinical determination of the actual site of the disorder.

A second prominent factor is that even perfectly healthy digestive organs may, as a result of purely functional derangement, simulate real organic disease.

Thirdly, prolonged functional disturbance of one or another digestive organ may eventually lead to actual organic changes. The transition may be very gradual until suddenly a catastrophe due to organic changes may take place. Since the afflicted individual had suffered only functional disturbances without any demonstrable lesion for many years, the physician who was somewhat indifferent to the existing syndrome is shocked by the sudden conversion of a psychic state into a real somatic state. The organs of the digestive tract are disturbed by psychic influences more readily than any other organ,²⁵

* Attending Physician, Beth Israel Hospital, New York City, Formerly Clinical Professor of Medicine, New York University College of Medicine

has been demonstrated by many physiologists and particularly by Wolf and Wolff.²

A fourth factor is existing disease in one organ of the digestive tract which may affect the function of other organs and eventually lead to organic changes in them. The frequency with which peptic ulcer, gallbladder disease and appendicular disease are encountered by the surgeon and the pathologist corroborates this fact, and led Roessle to speak of peptic ulcer as a disease secondary to chronic gallbladder or appendicular disease.

Our discussion of this topic will be confined chiefly to peptic ulcer with atypical symptoms and to chronic appendicular disease which may so simulate peptic ulcer as to make differential diagnosis difficult, if not impossible.

PEPTIC ULCER WITH ATYPICAL SYMPTOMS

Prior to Moynihan peptic ulcer was rarely diagnosed ante mortem. He was one of the earliest to emphasize the diagnosticable aspect of ulcer, particularly of the duodenum, and at one time thought that the history is of primary importance, the physical examination secondary. After extensive surgical and pathological experience, he came to realize that disease in the ileocecal region, and even such thoracic conditions as coronary artery disease, may simulate peptic ulcer. So he reversed himself completely and stated that even in cases of gastric hemorrhage one must often think "away from the stomach" when judging the cause of the catastrophe, for the lesion might be in other intra-abdominal organs. This last remark seems exaggerated but it is true on rare occasions, as will be illustrated below.

Braithwaite³ created the terms "gastroileac syndrome" and "ileo-gastric syndrome." By the former he meant a clinical condition where the disease lies in the stomach and the patient's symptoms are referred to the ileocecal region, by the latter he intended to signify pathologic change in the ileocecal region with the symptoms referable to the gastric area. It has been our experience that when the primary lesion, peptic ulcer in particular, is in the stomach proper, the symptoms are seldom referred to the appendicular region. If lower abdominal symptoms do exist, actual disease coexists in the ileocecal region. On the other hand, if the primary affection, with the exception of terminal ileitis, is in the ileocecal region, the symptoms are often referable to the epigastrium, even simulating fully those of gastric or duodenal ulcer.

Ulcer in the Asthenic Person—Some years ago Gross and Held⁴ cited a number of causes for atypical symptoms of ulcer of the ventriculum. The first of these was sensitiveness of the individual. In the asthenic person functional or nervous complaints may be so in the foreground as to mask entirely symptoms due to the ulcer. At one time severe headaches prevail, at another cardiovascular instability, or abdominal

has been demonstrated by many physiologists and particularly by Wolf and Wolff²

A fourth factor is existing disease in one organ of the digestive tract which may affect the function of other organs and eventually lead to organic changes in them. The frequency with which peptic ulcer, gallbladder disease and appendicular disease are encountered by the surgeon and the pathologist corroborates this fact, and led Roessle to speak of peptic ulcer as a disease secondary to chronic gallbladder or appendicular disease.

Our discussion of this topic will be confined chiefly to peptic ulcer with atypical symptoms and to chronic appendicular disease which may so simulate peptic ulcer as to make differential diagnosis difficult, if not impossible.

PEPTIC ULCER WITH ATYPICAL SYMPTOMS

Prior to Moynihan peptic ulcer was rarely diagnosed ante mortem. He was one of the earliest to emphasize the diagnosticable aspect of ulcer, particularly of the duodenum, and at one time thought that the history is of primary importance, the physical examination secondary. After extensive surgical and pathological experience, he came to realize that disease in the ileocecal region, and even such thoracic conditions as coronary artery disease, may simulate peptic ulcer. So he reversed himself completely and stated that even in cases of gastric hemorrhage one must often think "away from the stomach" when judging the cause of the catastrophe, for the lesion might be in other intra-abdominal organs. This last remark seems exaggerated but it is true on rare occasions as will be illustrated below.

Braithwaite³ created the terms "gastroileac syndrome" and "ileo-gastric syndrome." By the former he meant a clinical condition where the disease lies in the stomach and the patient's symptoms are referred to the ileocecal region, by the latter he intended to signify pathologic change in the ileocecal region with the symptoms referable to the gastric area. It has been our experience that when the primary lesion, peptic ulcer in particular, is in the stomach proper, the symptoms are seldom referred to the appendicular region. If lower abdominal symptoms do exist, actual disease coexists in the ileocecal region. On the other hand, if the primary affection, with the exception of terminal ileitis, is in the ileocecal region, the symptoms are often referable to the epigastrium, even simulating fully those of gastric or duodenal ulcer.

Ulcer in the Asthenic Person—Some years ago Gross and Held⁴ cited a number of causes for atypical symptoms of ulcer of the ventriculum. The first of these was sensitiveness of the individual. In the asthenic person functional or nervous complaints may be so in the foreground as to mask entirely symptoms due to the ulcer. At one time severe headaches prevail, at another cardiovascular instability, or abdominal

disturbances Only close questioning elicits symptoms suggestive of peptic ulcer in some cases Such individuals are vagotoniacs or vago-sympathicotoniacs (Eppinger and Hess) It is commonly known that in these people the functional disturbance can precede the organic disturbance by many years Gastric hemorrhage and even perforation may suddenly occur without any warning symptoms The disturbances of gastric function may vary Secretory disorders may be in the foreground, these are persistent pyrosis, regurgitation of sour fluid which awakens the patient at night, numbness of the gums due to the excess acid saliva, marked redness of the tongue or erosion of the pharynx, mouth and gums, and dullness of the teeth In other cases and/or occasionally in the same patient, sensory symptoms are outspoken The pain however, is not the hunger type or periodically recurring two or three hours after meals, it is persistent

When peptic ulcer is present, pain is usually elicited on deep pressure over the epigastric region or right hypochondrium However, the asthenic patient often finds relief by exerting deep pressure over that area himself Superficial pain, which may radiate to the intercostal region, is usually present, undoubtedly a vagosympathicotonic phenomenon As a rule, disease without pain except on deep pressure is organic, superficial pain is experienced by the sympathicotonic type of person

Very often the asthenic patient will show marked motility disturbance at certain periods Although there is no demonstrable roentgenologic lesion in the stomach or duodenum, there may be transient marked delay in the emptying of the stomach, or marked hyperperistalsis simulating pyloric stenosis Reexamination a day or two later may reveal normal emptying time of the stomach In some cases nausea so dominates every other complaint that it is clinically difficult to determine whether or not the cause is duodenal irritation on the basis of ulcer Boldyreff demonstrated physiologically that excess acid secretion causes irritation of the duodenum and nausea

In some instances, although pyloric stenosis is not demonstrable, nausea may be temporarily relieved by vomiting Riegel therefore described a "vomiting type of peptic ulcer" It is important to point out that he did not make the diagnosis of ulcer on the basis of clinical observations, but rather on the postmortem finding of ulcer in patients who had died of an intercurrent disease

Secretory, sensory and motility disturbances may occur at different times in the same individual, thus adding to the confusion and causing such individuals to be considered as hypochondriacs The present improved methods of diagnosis can guard the physician against such an error and prevent the further progress of the disease involving serious consequences

Ulcer in the Hypersthenic Individual—In contradistinction to the hypersensitive type occurring in asthenic individuals, there is the hyper-

sthenic individual who is usually hyposensitive and minimizes his symptoms. Sudden hemorrhage or even perforation may mark the first alarming symptom because the patient may have been allaying his pains by the use of alkalies. Close questioning after the hemorrhage may disclose the frequent use of bicarbonate of soda or some other proprietary drug.

The *mode of living* of the ulcer patient frequently contributes toward masking the existence of the disease. Some individuals exercise extreme denial of food, others eat to excess. A patient of the former group, after having responded to treatment following a hemorrhage, may continue to observe his diet to such an extreme that undernutrition, avitaminosis and marked enteroptosis may result. His symptoms eventually become unrelenting—a gnawing sensation in the epigastrium, plethoric patient who frequently is also a heavy smoker and a hard and myalgic pains in various parts of the body due to avitaminosis and anemia.

The second group, those who eat excessively, is exemplified by the plethoric patient who frequently is also a heavy smoker and a hard worker. The patient may suffer intermittent attacks of epigastric pain and the moment his symptoms subside he again partakes of large quantities of food, often regardless of quality, and even indulges in alcohol. Finally the condition becomes so aggravated that the pain is persistent. We had two such cases in a pair of brothers. Both of them developed carcinoma of the pylorus after many years. One brother had a gastroenterostomy, with three or four comfortable years postoperatively before carcinoma developed. The other was not operated on for ulcer. He later also developed carcinoma. After gastric resection he lived five years and eventually died from metastatic carcinoma of the liver.

The following is an illustration of a hypersthenic individual with extremely atypical ulcer symptoms.

A man, aged 45 years, gave a history of fifteen years' duration of attacks of pain in the upper abdomen terminating in nausea and vomiting which occurred only when a change in the weather took place. When the weather cleared he could eat almost everything without ill effects, but rain, snow or cloudy weather would cause recurrence of his gastric symptoms. X-ray examination showed a normal stomach; the first portion of the duodenum likewise did not show any characteristic abnormality of ulcer. The sole roentgenologic abnormality consisted of a small six hour residue in the stomach with the small intestines almost empty and the entire colon filled, despite the fact that the stomach was hypertonic and emptied rapidly during the early part of digestion. These were indirect signs of duodenal ulcer. Fluoroscopically there was no tender area over the epigastrium. The gastric acidity was normal.

After several weeks of treatment on the basis of ulcer the patient failed to improve and repeated x-ray examination revealed similar insignificant findings. Because of his long suffering he decided to submit to operation. We hesitated about advising surgery because the x-ray findings were meager and the symptoms atypical. Ulcer on the posterior wall of the duodenum was found and gastroenterostomy without resection was performed. He has been entirely symptom free for a number of years.

Although reports of ulcer sensitivity to weather have appeared in the literature, we feel that this case was singular in that the patient's pain was so severe that he insisted on an operation

Associated Gastric Catarrh—It is not uncommon to find that the symptom complex of peptic ulcer is effaced by an associated gastric catarrh. We are not in favor of the concept that catarrh precedes ulcer,⁵ but do agree that in some individuals where periodic pylorospasm causes retention, or the progress of the ulcer causes gastric retention, or where associated atony of the stomach is responsible for the retention, eventually gastric catarrh may develop. Such catarrh may be associated with either sub- or anacidity or hyperacidity. In these cases epigastric fullness or distress after meals, loss of appetite, nausea and extreme dryness in the mouth, coated tongue and bad taste in the mouth predominate. In other cases of this nature, pyrosis is persistent and the patient regularly resorts to the use of bicarbonate of soda or some other proprietary alkali for relief. The history will occasionally disclose typical ulcer symptoms several years previously. In these cases of gastric retention out of proportion to the real organic changes in the ulcer proper, the patient may improve temporarily with gastric lavage, antispasmodics and careful dieting. However, in most instances the symptoms recur, necessitating surgical intervention. Subtotal gastrectomy usually brings about curative results. A patient who refuses operation may have many years of fair comfort by submitting to frequent gastric lavage—for the first week, daily, for the next two months, two or three times a week.

Whereas it is true that, with the aid of the diagnostic methods at our disposal, particularly x-ray, one can establish the diagnosis in the vast majority of cases of peptic ulcer, it is equally true that in the absence of a peptic ulcer history and especially when the patient gives a confusing, vague history more indicative of neurosis than of organic disease, we often forego the x-ray examination and may miss the diagnosis.

Diagnosis Obscured by the Presence of Other Organic Disease—The following cases serve to illustrate how other organic disease in a peptic ulcer patient may greatly hamper the diagnosis of ulcer.

In one case of arrested pulmonary tuberculosis the patient was an extremely neurotic individual who had vague gastric complaints. Because of the existing tuberculosis and marked nervousness the diagnosis of duodenal ulcer was not suspected until sudden perforation of the ulcer necessitated immediate operation. Fortunately he recovered after a preliminary operation of suturing the ulcer, without resection, and is now comfortable after six years.

Another case is one of tight mitral stenosis with gastric complaints of many years' duration. The patient was eventually admitted to the Beth Israel Hospital in a state of congestive heart failure and he succumbed. At postmortem, in addition to the chronic valvular disease, a chronic duodenal ulcer was found.

An extremely atypical case is that of a patient (an artist) who for more than twenty years had vague gastric complaints without any symptoms suggestive of ulcer. He had a very marked epigastric hernia for which we advised repair but the patient refused to submit to surgery. For the last ten years he drank large quantities of alcohol and developed alcoholic neuritis. Under vitamin D treatment and withdrawal of the alcohol, he improved. However he reverted to alcoholic excesses and developed cirrhosis of the liver. He was admitted to the Beth Israel Hospital with extreme ascites, and shortly before death had a gastric hemorrhage. A ray examination of the esophagus had failed to reveal suspected varices as the origin of the bleeding. Autopsy showed, in addition to cirrhosis of the liver that a chronic duodenal ulcer was the source of the hemorrhage.

The relatively frequent presence of gastric or duodenal ulcer in cases of *cirrhosis of the liver* was noted by Patek and Ratnoff⁹

Pyloroduodenal adhesions or *gallbladder-duodenal adhesions* secondary to ulcer produce a misleading history. In such cases pain in the upper abdomen, radiating to the right side and right shoulder, and periodic attacks of severe epigastric pain due to pylorospasm may so simulate gallbladder disease that the diagnosis of duodenal ulcer is entirely effaced. In many such patients the gallbladder fails to concentrate the dye, adding further to the masking of ulcer symptoms. The x-ray findings and all symptoms are attributed to gallbladder disease. When the symptoms become so aggravated that surgery becomes essential, the lesion is found to be in the duodenum and the gallbladder is found to be perfectly normal.

The *ileogastric syndrome* (Braithwaite), when the disease is confined to the ileocecal region and causes reflex gastric symptoms, is a well established fact. A number of affections in the ileocecal region give rise to reflex gastric symptoms, such as tuberculous adenitis confined to the ileocecal region, or nonspecific adenitis where large calcified glands of a nonspecific nature (the remains of either an acute mesenteric adenitis or some chronic inflammatory condition of the cecum or colon) are present both in the ileocecal region and often in the right side of the abdomen. Also reflex gastrointestinal symptoms may occur in connection with ileitis as described by Crohn, Ginsberg and Oppenheimer, or in connection with chronic pelvic disease such as pelvic cellulitis or disease of the adnexa.

CHRONIC APPENDICITIS SIMULATING PEPTIC ULCER

None of the conditions already named ever cause gastric disturbance simulating fully gastric or duodenal ulcer. Chronic appendicular disease is the only pathological condition of the ileocecal region which may fully simulate peptic ulcer.

Chronic Appendicular Disease—a Clinical Entity—Many internists and surgeons today regard chronic appendicular disease as a nonexistent entity. That controversial group bases its argument on the fact that often, following appendectomy, the patient will continue to have the

same symptoms as before operation We strongly believe that in such cases there was a mistaken diagnosis, as in the recurrence of so-called gallbladder symptoms after cholecystectomy, where there has been neither serious disease of the gallbladder nor gallstones Every healthy organ must possess some function of greater or lesser importance, and its removal is therefore not only not beneficial but may be harmful On the other hand, both internists and surgeons encounter a large number of cases in which a definite clinical and roentgenologic picture of appendicular disease indicates surgery, and the removal of the appendix is extremely beneficial Such cases may have an associated pylorospasm or pyloritis, or a small erosion may exist in the pyloro-duodenal region which could not be demonstrated roentgenologically or surgically, but which was in need of medical care after the appendectomy

Mention must be made here of the work of Moynihan, Rolleston, Deaver, George D Stewart, Gibson (New York Hospital) and the recent work of M Behrend⁷ who were responsible for the establishment of the clinical entity of chronic appendicular disease

Anatomical Considerations—It may not here be amiss to review the anatomy of the appendix in general The appendix presents a small lined pouch attached to the tip of the cecum by its vascular and lymphatic supply which, in case of infection, spreads the noxious influence of the diseased appendix not only to the immediate neighboring viscera but also to the most distant parts of the body In view of these facts a pathological appendix becomes an unusual menace The appendix varies in length from 5.5 cm to an extreme length of 28 cm, is longer in young individuals than in those of later life The inner lumen is connected to the cecum by a reduplication of the folds of mucous membrane, described by Gerlach and known as the Gerlach valve

Contents passing from cecum into appendix and from appendix into cecum meet with no resistance unless the position of the appendix in relation to the cecum is such that communication of the contents between the two organs is not possible or in cases where the connection between them is pathologically obliterated Normally the passage of cecal contents into the appendix is very rapid It was shown experimentally that if lycopodium seeds are introduced into the colon by means of an enema it reaches the appendix within fifteen minutes Its shape and peristaltic activity indicate that it has the structure and function of the colon Even normally the appendix may contain some fecal matter, according to Aschoff, in about 60 per cent of cases Roentgenologic studies have demonstrated beyond doubt that a normal appendix fills and empties and changes its position and contour Conclusions may be reached that a diseased appendix quickly loses its elasticity and contractility, hence activity becomes diminished and the appendix may not be able to empty its contents and alter its shape and

position Persistence of dry fecal material and fecal stones in the appendix is an indication of disease Fecal matter may become so hardened as to form definite fecaliths which in turn may erode its mucous membrane and form a source of chronic erosion

The *blood supply* to the appendix is furnished by the ileocolic artery and is carried away by the ileocolic vein into the mesenteric vein This is important to point out because in case of appendicular disease the infectious material may reach the liver by way of the ileocolic vein and mesenteric vein, and give rise to dangerous consequences—thrombophlebitis of the portal vein and liver abscess Also, this furnishes an explanation for adhesions in cases of chronic appendicular disease, which may spread from the ileocecal region to the liver and cause enlargement of the liver and clinical symptoms pointing to disease in the right hypochondrium

The *lymphatics* form a meshwork in the submucosa through which a true connection between the lymphatic vessels, the mesentery and the peritoneum takes place These empty partially into the glands lying at the ileocecal angle and partially between the layers of the mesentery and its communicating glands Enlarged inflammatory glands may therefore occasionally be found in the vicinity of the cecum and ascending colon in some cases of chronic infection of the appendix The lymphatic vessels pass from the ascending colon and ileum to the upper surface of the liver and the ligament connecting it to the diaphragm, thus forming a communication between the lymphatics of the appendix and the subphrenic space, accounting for the existence, in some chronic cases of subphrenic adhesions or adhesions between the diaphragm and liver, and in acute cases of subdiaphragmatic abscess There is no lymphatic connection between the female generative organs and the appendix It had at one time been thought that affections of the generative organs could result secondary to appendicitis by direct extension through the lymphatics.

The *nerve supply* of the appendix is derived from the sympathetic fibers of the mesenteric plexus The numerous branches and nerves connecting with the nerve fibers of the gastrointestinal tract explain the fact that pains in chronic appendicitis may spread over all parts of the abdomen At times the ileofemoral nerve connects with the nerve supplying the appendix, in which instances pain associated with a pathological appendix may spread to the scrotum and to the right side of the thigh Under rare conditions the mucous membrane may atrophy after middle life leading to total or partial obliteration of the appendix The *narrowing* or complete occlusion of the lumen as well as the complete atrophy of the mucous membrane of the appendix is in a great majority of cases, a result of a previous inflammation which had led to fibrous tissue formation Aschoff demonstrated that before 10 years of age the appendix is obliterated in about 66 per cent of cases, up to 20 years of age, in 12 per cent, up to 30 years 20 per cent,

after 40 years, 28 per cent, after 50 years, 42 per cent, and after 60 years, 14 per cent

Pathology—The appendix has offered unusual opportunity for pathological study because it has been removed by surgeons during every possible stage of disease. The fact that the chronically diseased appendix is the result of a previously existing acute appendix is universally accepted. The pathological changes in a chronically diseased appendix depend upon the damage done during the acute stage plus the repeated recurrent attacks resulting from the infectious agent lodging in the organ. In order, therefore, to appreciate what pathological changes can take place in a chronically diseased appendix a few remarks about the changes in the acute stage are necessary.

In many instances, during the acute attack only the superficial epithelium of the distal part of the appendix is destroyed. The defect in the epithelium becomes covered with a fibrinous leukocytic exudate. This early stage can only be seen if the appendix is removed within a few hours after the attack. As a rule, such a stage progresses into a more complicated one. The infection penetrates into the grooves of the mucous membrane and thence often to the serous membrane of the appendix where it forms a leukocytic and later a fibrinous exudate. Aschoff applied the term "appendicitis phlegmonosa ulcerosa simplex" to this stage. If the process begins to recede the superficially destroyed mucous membrane together with the adhesions of the folds of the mucous membrane lead to stenosis, atresia and eventually to complete obliteration of the appendix. When it spreads to the serosa, adhesions to the ileum, cecum or even—depending on the length of the appendix—to distant organs like the generative organs, or to the liver, kidney, urinary bladder, hepatic flexure, spleen or sigmoid may result. True suppuration even to the point of abscess formation may take place in the lumen of the appendix, reach the serosa and become so encapsulated by fibrous tissue that it remains the source of chronic infection without giving rise to immediate surgical intervention.

The question whether a fecal stone may be present in a normal appendix or be the result of infection of the appendix, disabling it from ridding itself of the fluid fecal material and so causing fecal stone, is also a matter of considerable discussion. Aschoff maintains that fecal stone is usually superimposed upon an infection of the appendix. From the clinical standpoint it is important to remember that, although in some cases a fecal stone may be found in the appendix postmortem in cases in which the history does not point to appendiceal disease, a fecal stone is undoubtedly an indication of disturbed peristalsis of the appendix and is frequently the cause of appendicular colic.

In summation, changes in the chronic appendix may be those of stenosis, induration of the walls of the appendix, retention of mucus, fecal masses and fecal stones, and kinking by means of adhesions. These changes necessarily give rise to a varied clinical picture. In addi-

tion, the mesentery of the appendix is often contracted due to adhesions which invade the nerves and give rise to considerable pain, and occasionally forming real neuromas. In normal or obliterated appendices Maresch found distant neuromas which he attributes to involvement of the plexus of the submucosa by fibrous tissue, and which may give rise to considerable pain. In a few such cases in which operation was done at the Beth Israel Hospital, the pathologist, Dr. Plaut, demonstrated neuroma of the appendix. The process may extend to the wall of the cecum causing a moderately contracted and spastic cecum or it may cause catarrh of the mucous membrane and dilatation. At times pathological changes in the appendix may be the cause of diverticuli.

Chronic appendicular disease may also be caused by worms lodged in the appendix. Cecil and Bulkley described a characteristic form of appendicitis due to parasites, which consists of catarrhal inflammation with small hemorrhages. Actinomycosis as well as cancer may affect the appendix without affecting other organs. This is also true of periarteritis nodosa. Mucous substance may be found in the appendix and its mesentery and may form a tumor of considerable size, or the gelatinous contents may break through the appendix into the peritoneum or the appendix may undergo malignant degeneration.

Symptomatology—The symptoms of chronic appendicitis vary. In a small number of cases diagnosis is fairly easy because of a history of one or more recurrent attacks. In many cases, however, such history is lacking either because the attack occurred in early childhood and passed from memory and caused no later complications, or the attack in the adult may have been so mild that the patient did not consult a physician. However, mere tenderness over the ileocecal region with some vague gastric symptoms does not justify the diagnosis of chronic appendicular disease without a very careful physical and x-ray examination. It has been well established that a diseased appendix can produce definite symptoms of gastric or duodenal disorder with hardly any localized symptoms. Moynihan rightly termed these symptoms "appendicular dyspepsia," and Sir Humphrey Rolleston divided the symptoms of chronic appendicitis into four groups, namely (1) reflex (2) mechanical, (3) toxic, and (4) infective (discussed in detail by Held in 1924).⁸

In this communication we are chiefly concerned with the *reflex symptoms* particularly referable to symptoms simulating gastric or duodenal ulcer. These reflex phenomena may manifest themselves in secretory disturbance of the stomach in the form of hypersecretion and hyperacidity, chiefly of alimentary character, with symptoms of pyrosis, regurgitation of acid secretion and vomiting, in some cases there may even be continuous hypersecretion. The secretory disturbance can manifest itself by excessive mucus in the colon, giving rise to colica mucosa. Or it may spread to the salivary glands and cause

increased salivation Urinary symptoms may be the prominent complaint, particularly frequent micturition without increase of the quantity of the urine, which is the result of gastric hyperacidity with diminished acid in the urine or of alkalinity of the urine, either causing irritation of the urinary bladder

When *motor disturbances* are in the foreground, there is distress in the epigastrium, epigastric pressure shortly after meals, persistent belching and regurgitation of sour fluid, peristaltic unrest in the upper quadrant and in the cecum, rigidity of the cecum and of the rectus muscle overlying the cecum

More rarely, the motor disturbance manifests itself in atony of the stomach characterized by a splashing sound over the stomach and cecum and other signs of atony in the cecum such as persistent gurgling, more marked five or six hours after meals

If *sensory disturbances* predominate, the patient complains of persistent pain in the epigastric region often radiating to the thorax, but an indication of appendicular involvement is the fact that pressure over the appendicular region causes pain in the epigastrium (Aaron sign), and Head's zone is more marked over the appendicular region

In a patient who has both marked secretory and sensory disturbances, the differential diagnosis between ulcer and chronic appendicular disease is practically impossible It is quite likely that in such a case superficial gastric erosions may have resulted from the persistent hypersecretion, and is responsible for the pain

The following case histories are illustrative of chronic appendicitis simulating peptic ulcer

A physician had vague gastrointestinal symptoms for a long time He used alkalis frequently for relief of epigastric distress One afternoon, while in the operating room, he had a severe gastric hemorrhage After six weeks, during which time he was given several transfusions, he decided to submit to surgery Operation revealed a normal stomach and duodenum but marked adhesions were found around the ileocecal region and also a chronically inflamed appendix The patient made a complete recovery and remained entirely symptom-free

A 21 year old male suffered a severe gastric hemorrhage as the only symptom of disease The family history revealed that his mother had been operated on for ulcer and his sister had typical symptoms of peptic ulcer Several weeks after recovery from the hemorrhage, operation was performed, stomach and duodenum were entirely normal and a chronically diseased appendix was found

According to statistics from the Mayo Clinic, gastric hemorrhage occurs in about 2 per cent of cases of chronic appendicitis, the stomach being entirely normal

Cases similar to the above are cited in the literature on the subject Whereas hemorrhage in the peptic ulcer case is usually controlled, unless there is a pancreatoduodenal rupture, in cases of chronic appendicitis the hemorrhage tends to persist, causing severe secondary

anemia and checked only after repeated transfusions. In acute appendicitis marked hyperemia of the gastric mucosa with capillary oozing or thrombi is responsible for bleeding. However, in chronic appendicitis hemorrhage is a rare phenomenon and the underlying cause is unexplainable.

The symptoms of gastric or duodenal ulcer resulting from chronic appendicitis without bleeding are not uncommon. An important point in the differential diagnosis is the fact that when the extragastric disease is chronic appendicitis there is no periodicity of symptoms. The patient may have some comfortable days, but he is afflicted with symptoms practically most of the year. Patients who because of persistent pyrosis become addicted to large doses of alkalis eventually develop associated gastric catarrh. Very often one encounters in such cases the transient symptoms due to pylorospasm or irritation of the duodenum which causes true pyloritis and often duodenitis. The surgeon operating in such cases occasionally finds an unexplainable thickening of the pylorus which is undoubtedly due to repeated attacks of pylorospasm causing some hypertrophy of the pylorus. Removal of the appendix may produce relief temporarily. However, resumption of errors in diet or exposure to emotional strain will lead to recurrence of the symptoms. One may even clinically suspect that the persistent pyloritis or duodenitis may later lead to true ulcer formation of the pylorus or duodenum if the patient is not treated both dietetically and emotionally on the basis of ulcer after the appendectomy. Not infrequently, after removal of a chronically diseased appendix although the surgeon made a very careful search during operation and found no ulcer, several months later the patient has been known to return with ulcer symptoms, and x-ray has revealed the presence of a gastric or duodenal ulcer. In explanation one may assume that a previously existing irritation of pylorus or duodenum was the focus for the development of the ulcer.

Direct Physical Signs—The diagnosis of chronic appendicitis is of the utmost importance because if the appendix is diseased the only possible cure is the removal of the organ. From the symptoms alone it is very difficult to establish a positive diagnosis. Some of the leading physical signs which aid in diagnosis are the following:

1. Tenderness in the ileocecal region, especially on deep pressure.
2. Rigidity of the right rectus muscle which is often present in chronic cases also. This is especially marked if there are pericecal adhesions.
3. Pressure in the appendicular region causing pain in the epigastrium (Aaron's sign).
4. Tenderness over the ileocecal region when the colon is inflated with air (Bastedo sign).
5. Rieder sign which consists of tenderness over the appendicular region on rectal examination.

6 Pain over the appendicular region if deep pressure is exercised over the left side at a point corresponding to McBurney's point on the right side

Within our own experience we have observed many cases in which a chronically diseased retrocecal appendix gives rise to spontaneous pain in the right loin. Upon exertion of pressure over the point of spontaneous pain, referred pain is experienced in the appendicular region.

Roentgenologic Examination—Its Importance—Careful clinical and roentgenologic examinations are of primary importance in determining whether a diseased appendix is the actual and sole cause of the ulcer symptoms. The clinical examination alone will often not be conclusive, so that roentgenography is the deciding means of ruling out gastric or duodenal ulcer. We need not go into detail about the x-ray phenomena of gastric or duodenal ulcer, but suffice it to say that if thorough roentgenologic study is done, including the mucous membrane of the stomach and the first and second portions of the duodenum, one can determine with a fair degree of certainty the presence of an ulcer. This is particularly true of duodenal ulcer where the x-ray diagnosis is conclusive in 95 per cent of cases. Mucous membrane studies are an outstanding aid in the diagnosis of gastric ulcer.

X-ray study of the motor phenomena of the stomach and duodenum is especially valuable when gastric or duodenal symptoms are due to some extragastric factor, particularly chronic appendicitis. Quite often one encounters in such cases persistent pylorospasm indicated by the marked narrowing of the pylorus due to spasm of the sphincter pylori. In the course of fluoroscopy, or during the taking of films, fifteen to twenty minutes may elapse before some contrast reaches the duodenum. At times partial gastropasm is encountered. In other instances the duodenal irritation is manifested by either its spasticity or slight irregularity both on the lesser and greater curvatures. Such phenomena are usually transient, they are evident in the earlier part of digestion, but disappear entirely within an hour or two and a good outline of the duodenum is obtainable. Other x-ray evidence of motor disturbance consists of four, five and six hour residue in the stomach in cases of chronic appendicitis.

Direct Roentgenologic Signs—From the roentgenologic standpoint it is important to observe carefully the filling and emptying of the appendix, its shape, position, mobility and motility, spasm, tenderness under the fluoroscope, and the presence of concretions.

The patient is to be examined, films taken after four, six, twenty-four and forty-eight hours and if the appendix remains filled, as late as seventy-two hours. A normal appendix empties and fills repeatedly during the course of the examination. If the appendix remains persistently filled there is reason to attribute pathological significance to it.

The abnormal appendix may be shortened, thick, at times as wide as it is long, the shape and position not altering throughout the entire course of the examination. The shortness and thickness do not necessarily indicate that the diseased appendix is not longer than seen on the roentgenogram. But it does indicate that the lumen of the appendix is obliterated in some of its parts and therefore only the upper part fills with the contrast substance.

An abnormal appendix may be unusually long, fixed and persistently filled. The position of the appendix varies even physiologically, and a malposition of the appendix is of pathological importance if it remains fixed and is tender when examined fluoroscopically. Certain malpositions of the appendix, however, invariably indicate pathologic changes, namely: if the appendix is pulled to the left side or low down into the pelvis, or to the region of the urinary bladder, or up to the retrocecal region. The presence of concretions indicates that the appendix cannot successfully empty itself of its contents, and that there is disease of its mucous membrane. A persistently kinked, coiled appendix that does not alter its shape is likewise an indication of disease.

There are also other direct signs which are the result of adhesions caused by a diseased appendix. These are either a very low or very high position of the cecum, restricted mobility of the cecum, pulling of the sigmoid to the right or pulling of the cecum to the left. At times the cecum and the appendix are so pulled to the left by adhesions that the patient has pain over the left lower quadrant and the surgeon in reality unravels a so-called left-sided appendix. Sometimes the appendix, by adhesions, spreads to the transverse colon pulling the transverse colon downwards and causing kinking of the hepatic flexure. The adhesions may cause a matting together of the ileum with the cecum and in these cases there is ileal stasis beyond twenty-four hours, and very marked ileocecal valve incompetency—although the ileocecal valve incompetency by itself is no indication of disease. Very often bubbles of gas are encountered in the lower ileum likewise due to the ileocecal adhesions.

Indirect Roentgenologic Signs.—Indirect roentgenologic signs are much less reliable, but worthy of mention. They consist of unexplained ileal stasis due to spasm of the ileocecal valve, cecal stasis, spasticity or atony of the cecum, spasm of the pylorus and often spasm of the greater curvature of the stomach if pressure is exercised over the appendicular region under the fluoroscope.

CONCLUSIONS

1 Attention has been directed to the differential diagnosis of gastric or duodenal ulcer and chronic appendicitis especially as it pertains to these diseases when the symptoms are extremely atypical.

2 Gastric or duodenal ulcer seldom causes symptoms referable to

the ileocecal region. On the other hand, the ileogastric syndrome, where the lesion is in the appendix or in the ileocecal region, does frequently simulate gastric or duodenal ulcer.

3 Hemorrhage occurring in cases of chronic appendicular disease is more resistant to medical treatment than hemorrhage due to peptic ulcer, and gives rise to a protracted anemia. Removal of the diseased appendix may permanently relieve the gastric symptoms.

4 Symptoms simulating gastric or duodenal ulcer, due to chronic appendicitis, have a greater tendency to persist throughout the entire year with very transient relief.

5 In cases of pylorospasm and duodenitis, if the diseased appendix is removed, it is essential to treat the patient postoperatively, both dietetically and emotionally for a long time, in order to prevent recurrence of gastric symptoms or the possibility of eventual ulcer formation.

6 In the differential diagnosis, in addition to the clinical symptoms, there must be careful roentgenologic study of the ileocecal region with particular emphasis on the appendicular region.

DIVERTICULOSIS AND DIVERTICULITIS A CLINICAL STUDY OF THE COMPLICATIONS

KIRBY A. MARTIN, M.D., F.A.C.P.* AND
CHARLES G. ADST, JR., M.D.†

THE purpose of this clinic is to present some data on diverticulosis of the gastrointestinal tract and to comment on the complications and treatment of diverticula of the colon—diverticulitis, hemorrhage, perforation and intestinal obstruction

LOCATION PREVALENCE AND AGE

Diverticula may be found in any part of the intestinal tract, only occasionally in the esophagus, stomach and small intestines, more frequently in the duodenum and very commonly in the colon, especially in its distal half. They may be congenital (Meckel's) but usually are acquired, if the latter, they are frequently multiple.

Diverticula have been known to the anatomists as a rare finding for centuries, but the first description of them as an entity was that of Sommering in 1794 and Chuvellier in 1849. Virchow in 1853 was the first to define them clinically. It was not until 1898, however, that a case of perforated diverticulitis with resulting left-sided peritonitis was reported by Graser. Lewald in 1914 is credited with the first roentgenologic diagnosis, but the prevalence of diverticula was not fully appreciated until the opaque motor meal x-ray technic became a common diagnostic procedure. Their importance as a clinical entity is still in a process of evolution.

X-ray and postmortem examinations of the intestinal tract have shown diverticula to be uncommon before the age of 35 and increasingly frequent after 45 years. The incidence is usually stated to be higher in the male than in the female, also more common in the obese. They are frequently seen proximal to a partial obstruction. Numerous authors have stated that they are found in about 5 per cent of persons subjected to x-ray examination for any cause.

Kocour¹ studied the incidence of diverticulosis in 7000 consecutive autopsies, and gives the percentage in each age decade. His figures show the condition to increase markedly in frequency after the age of 40, and to become relatively stationary after the sixtieth year. Of the patients over 40 years of age, 3.58 per cent showed diverticulosis.

† Assistant Attending Physician, Outpatient Department, St. Luke's Hospital.

and 0.15 per cent showed some complications which had caused the death of the patient. Contrary to most observations, his data show the incidence of diverticulosis in the female to be 33 per cent higher than in the male.

Diverticula, when once formed, persist. Only occasionally do they produce symptoms. The patient whose colon is x-rayed usually has some symptoms to justify the procedure and then the failure to show diverticula does not necessarily disprove their presence. They may fail to fill at times, as does an appendix. It would thus follow that consecutive autopsies in a large series, in which special attention was paid to this condition, would be more likely to represent the true incidence of the disease than conclusions based upon clinical findings. It is interesting that Kocour found the incidence of gallbladder disease in persons over 40 years of age to be double in those also having diverticulosis.

PATHOGENESIS

Anatomically, diverticula are blind sacs with small bases branching from the gastrointestinal tract. The pathogenesis is still incompletely understood. There is a common belief that the herniations occur at the point of entrance of a blood vessel into the wall of the bowel. To support this thesis, diverticula are frequently seen to develop in two parallel rows on either side of the mesocolon. Fansler² disagreed with this concept and stated that it is unusual to find a blood vessel adjacent to the neck of a diverticulum, especially in the colon. It is his opinion that diverticula develop in the haustrations or sacculations of the colon, in the wall of which only one layer of muscle (circular) is found. In these haustrations, the susceptibility of the muscular wall to stretching and thinning is increased, especially in the descending colon and sigmoid where the intestinal tension is greatest. This stretching and thinning in older individuals he believes may result in herniation and formation of diverticula. In agreement with this is the experience of not infrequently finding diverticula on any or all sides of the colon. The wall of the diverticulum is therefore formed from mucous, submucous and peritoneal coats, and at times acquires a fatty coat.

DIVERTICULITIS

Diverticulosis which precedes diverticulitis is present, as previously stated, in about 5 per cent of persons subjected to x-ray examination of the colon for any cause. Diverticulitis develops in about 12 to 15 per cent, according to Graham.³ In other words, diverticula cause no symptoms in most instances. They are, however, potential sources of danger in producing localized stasis, inflammation and ulceration of the sac, with possible perforation. The sigmoid and descending colon are the most common areas to meet with these complications.

DIVERTICULA OF THE SIGMOID AND DESCENDING COLON

Further discussion in this clinic will be limited to the consideration of symptoms, diagnosis and treatment in the complications of diverticulosis found in the sigmoid and descending colon. The statistical data to be presented were obtained by reviewing the material in the record room of the New York Hospital. The selected case records were taken from our private files. The opinions expressed obviously are wider than the analysis of the material would permit.

TABLE 1—DATA CONCERNING DIVERTICULITIS AT NEW YORK HOSPITAL,
1933 TO 1944*

Total admissions to New York Hospital	177 718
Cases of diverticulitis	201
Percentage of admission	0.001
Sex	105 males, 96 females
Duration of symptoms	2 hours to 54 years

Carcinoma found	4	7.8
Deaths from carcinoma	3	5.9
Deaths excluding carcinoma	0	0

SYMPTOMS AND DIAGNOSIS

The symptoms vary greatly, from a single slight acute attack, recurring episodes or chronic inflammatory reaction, to acute or chronic perforation with localized peritonitis and abscess formation or general peritonitis. A fistula occasionally develops between the sigmoid and the vagina or the urinary bladder, the latter manifesting itself by the urine containing gas and fecal material.

Local manifestations, if present, are usually in the left lower quad-

rant of the abdomen, but may be in the midline or to the right side, depending upon the position of the sigmoid and its tension, a spastic sigmoid may produce back pressure in the cecum and appendix, and the latter may be blamed for the symptoms. Pain on pressure over the sigmoid, muscle guard, spasm and flatulence are common. The symptoms usually give little information as to the extent of the lesion unless a tumor mass is felt.

In other instances a dull intermittent or constant cramplike diffuse pain in the abdomen frequently associated with tenesmus is common, or the symptoms may be entirely rectal. A significant sign is the temporary relief that may follow a warm saline enema, a bowel movement or the passing of flatus. Fever and leukocytosis may be present. Diarrhea and constipation are equally common. Rectal bleeding does occur, but is rare except in Meckel's diverticulum, it may follow the passing of diverticular concretions, but blood in the stool indicates carcinoma until disproved.

The clinical picture associated with diverticulitis can simulate almost any other abdominal disease. The importance of making a proper diagnosis is therefore obvious, operation is rarely advised in diverticulitis. Furthermore, the postoperative mortality was 20 per cent, with a residual mortality of 29 per cent in Babcock's⁴ series. In our series it was 23.5 per cent. X-ray study is indispensable in this work and if used to its fullest extent, fruitless surgical procedures can be avoided.

DIFFERENTIAL DIAGNOSIS

In most cases it is easy to distinguish carcinoma from diverticulitis, difficult in a few, and almost impossible in an occasional case. In this latter group exploratory laparotomy may be necessary. The operator frequently encounters a hard, irregular, fixed mass involving the sigmoid or descending colon and the diagnosis may remain uncertain pending the microscopic study. Carcinoma, like diverticulosis, is most commonly found in the sigmoid and descending colon, although the association of the two is so rare that there is no reason to believe that diverticulosis is a precursor of cancer.

Proctoscopic examination is indicated. It is not uncommon to find a carcinoma of the rectum producing the symptoms, although the radiographs may be negative save for the presence of diverticula or perhaps diverticulitis of the sigmoid.

Blood, pus and excess mucus with a foul odor coming from some point higher than the rectum usually means carcinoma, but occasionally an intramural abscess in peridiverticulitis will give a similar picture if the abscess is draining into the gut. In all such cases a complete gastrointestinal study is indicated.

Radiographic study is a valuable adjunct in the diagnosis of diverticulitis, in most cases it is all that is necessary. In complicated cases, however, the responsibility for the differential diagnosis is great. Still

the balance of evidence is in the interpretation of the radiographic findings, but the clinician who marshals all the clinical data in a given case will err less frequently

In acute uncomplicated cases the inflamed, edematous walls present a bizarre sawtooth outline giving such a characteristic radiograph, during a barium enema, that it is not likely to be confused, even though no diverticula are seen (Case III) But diagnosis is more difficult in acute exacerbation of a chronic diverticulitis, a subacute or chronic peridiverticulitis which has produced a thick wall and a constricted lumen of the gut with cone-shaped ends (Case VII, *A*) There is usually a distortion of the pattern of the mucosal folds and a marked deformity of the bowel lumen (Case V) Air contrast enema and spot films of mucosal pattern are usually helpful in such cases Still more complicated are those that develop intramural abscesses, losing part of the mucosal pattern (Case VII, *B*) Diverticula with long necks are common in such cases, and if they should fall at either end of the constriction, they may produce an overhanging edge like that seen in carcinoma The two conditions do coexist occasionally and the presence of diverticula proximal or distal to the constricted area does not exclude carcinoma, as illustrated in Case IX

The presence of diverticula does not help much in the differential diagnosis, but their absence does if proper delayed x-ray films are made following an opaque motor meal However, the presence of diverticula in the constricting mass is important because they rarely if ever occur in carcinoma (Schatzki⁶) (Case VIII)

TREATMENT

The treatment is medical in all but those few cases in which serious complications may or do occur The predominant symptom in the average uncomplicated case is *spasm* of smooth muscle, the result of inflammation in the diverticula The duration or intensity of the symptoms is such that only an occasional patient consults his physician In more severe cases the following treatment is usually effective Rest in bed, heat to abdomen, smooth diet, sedative, antispasmodic and inducing bowel movement with the least possible irritation Phenobarbital gm 0.032 ($\frac{1}{2}$ grain), three times a day, or tincture of belladonna 1.9 cc (30 drops) single or combined (we have never been impressed with the virtues of the latter) Mineral oil is beneficial during the acute phases, at the expense of a possible avitaminosis Codeine 0.06 gm (1 grain) or paregoric 4 cc (1 dram) may be indicated Warm saline or oil enemas usually give comfort Barium sulfate in 28.4-gm (1 ounce) doses, given in a water suspension two or three times a week is beneficial The barium supposedly displaces the irritating, fermenting intestinal content, reducing the inflammation and edema The improvement of symptoms that so frequently follows x-ray study of the colon amply confirms this statement

Obstruction develops slowly as a rule, and is rarely complete. It may be the first symptom. The treatment is secondary to the diverticulitis. We encountered this only eight times in our series.

Acute perforation has been rare in our experience. It has been stated to occur about one half as often as perforation from carcinoma. We had eight cases. Acute perforation from a diverticulum in the colon, like acute perforation from any cause, calls for immediate operative closure. These patients usually do well.

Fig. 125 — (Case I.)

Slow perforation Perforation from a diverticulum or an intramural abscess is more common than acute perforation and, unlike an appendix, is likely to produce few symptoms for long periods of time, due to a slow but complete walling-off process.

The sulfonamides have not been impressive, in our experience, in the uncomplicated cases or in those that perforate and form abscesses or fistulous tracts. Likewise in our limited experience, penicillin was beneficial only in secondary complications (Case VII, B).

This group likewise is managed surgically. The exploratory laparotomy, as well as the postmortem findings, in these cases usually

shows a widespread mesentery and lymph gland inflammatory involvement. This, in addition to abscess and sinus tracts, makes resection of the affected segment of the gut a hazardous task.

CASE REPORTS

CASE I

Clinical Woman, 53. Loss of 15 pounds of weight. No intestinal symptoms.

Normal bowel function.

Film (Fig 125) 24-hour barium motor meal.

Diagnosis Diverticulosis of colon.

Accessory Osteogenesis imperfecta, has had fourteen fractures.

Fig 126 — (Case II)

CASE II

Clinical Man, 55. Vague abdominal distress for ten years, worse in past three months.

Film (Fig 126) 24-hour barium motor meal. In transverse colon note "pseudo-diverticula." Barium enema films showed no evidence of organic disease.

Diagnosis Duodenal ulcer, right renal calculi. Spastic colon.

CASE III

Clinical Man, 51. Acute abdominal pain, typical "left side appendicitis." Six years later, no further symptoms.

Film (Fig 127) Barium enema (film reversed). Note spasm in sigmoid, spikes set at varying angles to the lumen. No diverticula seen in sigmoid, one noted in transverse colon. On delayed films two small diverticula were seen in sigmoid.

Remarks Typical of acute, early diverticulitis.

CASE IV

Clinical Man, 51 No intestinal symptoms until ten hours before. Onset with acute left lower abdominal distress and a sudden desire to defecate and pass flatus. Diarrhea lasted three hours, followed by frequent periods of straining and tenesmus but passing only small amounts of mucus and bright red blood.

Proctoscopic From some point above the rectosigmoid area mucus and bright red blood came into view otherwise the examination was negative.

Fig 127—(Case III.)

Film (Fig 128) Barium enema. Note spasm in sigmoid with spikes set at various angles to the bowel lumen. (Postevacuant film showed four small diverticula.)

Diagnosis Acute diverticulitis of sigmoid with hemorrhage

Result Symptoms subsided

CASE V

Clinical Man, 55 Many attacks of left lower abdominal distress none in acute phase, until now.

Film (Fig 129) Postevacuation barium enema, plus air injection. Note spiral stair effect from deep folds of mucosa. Diverticula are at apices of these folds.

Diagnosis Acute phase of chronic diverticulitis.

Fig 128 —(Case IV)

Fig 129 —(Case V)

CASE VI, A

Clinical Man, 55 Generally constipated During past ten years repeated attacks of diarrhea and lower abdominal distress Now, temperature 100° F, pulse

95, white blood cells 11,000 pain in left lower quadrant. Desire to defecate and pass flatus slight muscle guard Palpable mass in left lower quadrant.

A

B

Fig 130—(Case VI)

Film (Fig 130 A) Barium enema. Narrowing of the sigmoid lumen with a symmetrical arrangement of diverticula with long necks, "accordion type"
Diagnosis Acute exacerbation of a chronic diverticulitis, peridiverticulitis.

CASE VI, B

Same case four years later, following operation for acute perforation at the proximal end of narrowing Patient had been asymptomatic for nine months

A

B

Fig 131 — (Case VII)

Film (Fig 130, B) Barium enema Funnel-shaped shadows at base of some diverticula, probably fecalith

Comment Prognosis is poor, resection advised

CASE VII A

Clinical Woman 63 Constipated treated fifteen years for "colitis" First symptom was acute, severe rectal pain Temperature 104 F., pulse 140 white blood cells 18 000 No abdominal signs or symptoms. Rectal and vaginal examination negative save for general discomfort. Later stool contained blood and pus

Film (Fig 131 A) Barium enema. Filling defect in sigmoid colon much spasm partial intestinal obstruction. Note numerous diverticula with long necks at unusual distances from the central axis of the gut.

Diagnosis Diverticulitis, acute phase of a chronic peridiverticulitis, intramural abscess and question of perforation of a diverticulum with pelvic abscess partial obstruction of colon.

Fig 132 —(Case VIII)

CASE VII B

In same case two days later a sigmoid vaginal fistula developed Temperature subsided and general condition improved until a four year old osteomyelitis of leg became active Sulfonamides had no apparent effect on abscess or osteomyelitis One million units of penicillin effected a quick subsidence of the osteomyelitis but had no demonstrable effect on the pelvic abscess.

Film (Fig 131 B) 36-hour barium motor meal plus barium enema. Note evidence of intramural abscesses and a fistulous tract to pelvic abscess indicated by arrows

Outcome Resection of sigmoid colon three months following a colostomy Patient died thirty-six days postoperatively of general peritonitis and sepsis.

Surgical Pathology Specimen removed at operation showed an 18-inch segment of colon 12 inches of which were dense, firm and greatly thickened with many diverticula, intramural abscesses and intramural fistulas, some communicating with the lumen of the bowel and one to the external surface

CASE VIII (Courtesy of Dr Frederic Bancroft)

Clinical Woman, 80 Intermittent attacks of left lower quadrant pain for forty years Lost 15 pounds in last seven months, abdominal distress worse. Diarrhea, with blood in stool Palpable mass in left lower quadrant.

Film (Fig 132) Fixed irregularity in outline of descending colon with eccentric lumen Mucosal pattern destroyed No diverticula seen in area of filling defect but are numerous distal to same Note large soft tissue shadow indicated by arrows Probably a cyst, had no relation to colon, was not explored

Diagnosis Carcinoma of colon with partial colonic obstruction Diverticulitis chronic type

Operation Resection of descending colon and sigmoid-anastomosis, colostomy closed

Pathology Diagnosis—adenocarcinoma of colon, peridiverticulitis of colon

Result Discharged home—bowel function normal

Fig 133 —(Case IX.)

CASE IX

Clinical Man, 53 Moderate constipation for several years, with many attacks of vague abdominal distress Since past ten months has had tendency toward diarrhea, more recently has had blood in stool, no weight change

Film (Fig 133) 36-hour motor meal, plus barium enema Large constant filling defect in descending colon with partial colonic obstruction Note numerous diverticula with long necks on medial side of filling defect and no diverticula lateral side, save one at upper border producing an overhanging edge, mucosal pattern destroyed

Diagnosis Diverticulitis, peridiverticulitis of descending colon and sigmoid with colonic obstruction, question of carcinoma of descending colon

Operation Resection and end-to-end anastomosis Specimen showed a chronic peridiverticulitis with an ulcerating carcinoma on lateral wall

Result Recovered

COMMENT

In practice many cases of colonic disturbance are labeled and treated as "colitis" without proper examination and study. Most will prove to be functional, but an occasional one will have an organic lesion responsible for the symptoms. A significant point to suggest the latter is *a change in the bowel rhythm, a change in the rate of flow* (diarrhea or constipation) or *a change in character of the content* (increase or decrease of fluid, presence of blood, mucus or pus). Diagnosis is the first consideration.

It is to be borne in mind that this study, for the most part, represents only the occasional case of diverticulitis in which the patient was sufficiently ill to be admitted to the hospital. The disease is very commonly met in ambulatory practice and rather infrequently in hospital practice.

The severity of the symptoms gave no clue in most instances as to the stage of the disease process. This fact has a tendency to lessen the percentage of severe complications to the total group. And, for the same reason, a large percentage responded well to medical treatment.

Acute perforations, when they did occur, were frequently found in the absence of other complications, such as peridiverticulitis, and if recognized early, usually did well following operative closure of the perforation.

In the group in which peridiverticulitis was the predominant feature, partial colonic obstruction, slow perforation with abscess formation and fistula were common complications. Our data support the view that there has been no significant change in the mortality rate in this group in twenty-five years, despite the general progress in medical management in many other conditions. Peridiverticulitis and carcinoma are most commonly found in the descending and sigmoid colon. They also have in common the same age group. The treatment of diverticulitis is generally considered medical, carcinoma surgical. In several instances a preoperative positive diagnosis was impossible and a resection of the lesion was carried out. In Table 4 you will note that there were thirteen operations on such cases and only four carcinomas were found. If we exclude these four carcinomas the mortality drops to 0 against 22.9 in the group as a whole. The difference lies in the fact that infection as a complication was infrequent. The fault, therefore, would appear to lie in the continued failure to recognize those cases with impending danger as a separate group and institute proper surgical measures. This is a serious criticism of our diagnostic acumen, but improvement will follow if operation is offered early as a preventive of a too-often widespread infection and fatal outcome.

SUMMARY

During the period between 1933 and 1944 there were 201 patients with acute diverticulitis admitted to the New York Hospital in a total admission of 177,718 patients, or 0.00112 per cent

There were 28 cases of Meckel's diverticulum, or 0.00016 per cent. Fourteen patients were operated on with no postoperative deaths

There were 51 cases operated on for some complication in relation to the diverticulitis with 12 deaths, or 23.5 per cent

Carcinoma was encountered in the presence of diverticulitis in 4 cases, or 7.8 per cent

Carcinoma was suspected and operation carried out on 13 cases (25.5 per cent), with 3 deaths, or 5.9 per cent. Excluding carcinoma, it was 0 against 23.5 per cent in the group as a whole

Peridiverticulitis, like carcinoma, occurs in the same age group and is most commonly found in the descending and sigmoid colon. The lesion formed is frequently confused with carcinoma and may lead to serious complications, followed by a high mortality rate. Data are presented to suggest how a differential diagnosis can be made and how the mortality rate can be lowered

TREATMENT OF CIRRHOSIS OF THE LIVER BY NUTRITIONAL MEANS

NORMAN JOLLIFFE, M D * AND ELMER ALPERT, M D †

NUTRITIONAL DEFICIENCIES AS BASIS OF CIRRHOSIS OF LIVER

THE basic difficulty in formulating an effective treatment for cirrhosis of the liver has been our ignorance of the pathogenesis of this disease. In the past decade, however, some evidence has been presented showing that cirrhosis of the liver may have its pathogenesis in some form of malnutrition Jolliffe and Jellenik,¹ after reviewing the literature, point out that the weight of scientific evidence dismisses the direct causation of cirrhosis by alcohol

Cirrhosis of the liver has been produced experimentally by dietary means The lack of certain factors contained in yeast^{2 3 4} or casein^{5 6 7 8 9} brings about fibrotic changes in the livers of rats and rabbits Fatty infiltration and cirrhosis have been produced by diets low in protein and high in fat.^{4 7 8, 10} Low protein, choline-poor diets produce cirrhosis of the liver in rats which is characterized by fatty infiltration and the appearance of a hyaline substance in the liver cells⁶ Addition of choline, a high casein diet or choline with a high casein diet produced regression of the fatty changes and regeneration of liver cells¹¹ The feeding of excess cystine¹² also is said to produce liver cirrhosis in experimental animals Halliday¹³ was able to demonstrate an increased liver lipid content in rats deficient in vitamin B₆ as compared with normal animals Fouts⁹ produced a deficiency state in dogs in which fatty cirrhotic livers occurred on a low protein diet supplemented with thiamine, riboflavin, nicotinic acid, pyridoxine and a pantothenic acid which could be improved by the administration of liver extract.

Nutritional deficiencies as a basis of cirrhosis of the liver were suggested even before vitamin deficiencies had received consideration Klieneberger¹⁴ attributed the severe forms of cirrhosis to poor nutrition in 1923, and ten years later, Kennedy¹⁵ suggested that alcohol acted more as a factor contributing to dietary deficiency than as a toxic substance Connor¹⁶ reporting the results of his classical experiments on dogs, stated, "There can be little doubt now that alcohol and the habits induced by the consumption of large amounts of alcohol

Associate Professor of Medicine, New York University College of Medicine, New York City Formerly Chief of the Medical Service of the Psychiatric Division of Bellevue Hospital

† Passed Assistant Surgeon (R) United States Public Health Service. Formerly Resident Physician, Medical Service, Psychiatric Division, Bellevue Hospital

are the most important factors concerned with the production of fatty liver which passes on in some cases to cirrhosis "

Alcoholic patients with cirrhosis often have been on deficient diets for long periods of time, and the incidence of certain deficiency states in liver cirrhosis is not small. Peripheral neuropathy¹⁷ and signs of niacin deficiency¹⁸ occur in a high percentage of cases of cirrhosis. Patek¹⁹ found polyneuritis in 40 per cent and a smooth tongue in 60 per cent of fifty-four patients with cirrhosis of the liver. The cirrhotic often enters the hospital exhibiting one of the types of alcoholic encephalopathy for which an avitaminotic etiology has been postulated.^{20 21} In 200 cases of cirrhosis of the liver on the Medical Service of the Psychiatric Division, Bellevue Hospital, 20 per cent of the patients were in the encephalopathic state on admission, including Wernicke's syndrome, nicotinic acid deficiency encephalopathy, the Korsakoff psychosis and nonspecific alcoholic encephalopathies. Not alone the vitamin B complex but also a deficiency of vitamin K is found concomitant with the cirrhotic state. A lowered prothrombin level in cirrhosis has been found by several groups of investigators.^{22 23 24} This is due to the fact that the liver is responsible for the utilization of vitamin K in the synthesis of prothrombin.

Other manifestations of the cirrhotic syndrome emphasize its nutritional relationship. The presence of ascites is one of the most important determining factors in prognosis and is usually, but not always, associated with demonstrable changes in the serum proteins. The total proteins are reduced, or if normal, the albumin fraction is decreased with a compensatory increase in globulin, resulting in an inversion of the albumin-globulin ratio. Since Starling²⁵ pointed out the role of the serum protein in the maintenance of the colloid osmotic pressure of the blood, several workers^{26 27} have shown a correlation between the reduced level of serum albumin and the accumulation of ascites. Post and Patek,²⁸ from a study of the serum proteins in cirrhosis of the liver found that the changes in level of the serum albumin have a good correlation with the clinical course. In those patients whose course is unfavorable, the serum albumin either remains low or declines.

Recently, a definite relationship has been pointed out between vitamin B and serum proteins in edema. Field²⁹ observed cases with edema and lowered plasma protein despite diets apparently adequate in both proteins and vitamins. Relief followed supplementation with vitamin B complex. These include cases of cirrhosis of the liver, in one of which the patient has been maintained edema-free and with nearly normal serum protein despite increasing impairment of liver function.

Anemia may be present in from 40 to 90 per cent^{18 30, 31} of the patients with cirrhosis of the liver. It is frequently of the hyperchromic, macrocytic types found in pernicious anemia. This finding is probably due to the inability of the damaged liver to store the anti-anemic factor.

Cirrhosis of the liver may occur in association with many factors which act as hepatotoxic substances, such as chemical poisons, syphilis, a variety of systemic diseases, hyperthyroidism, toxemia of pregnancy and toxins of intestinal origin. The experimental studies demonstrate that it is difficult to produce permanent and severe parenchymatous liver disease except when the liver is in an abnormal state. It may well be that the factor common to the action of all hepatotoxic substances in the production of cirrhosis is in some altered chemical state caused by the poor nutrition of the liver. It might be well, therefore, to mention briefly some of the more important factors which can protect the liver from the adverse action of numerous toxins.

Studies on experimental animals have demonstrated the lipotropic action of several factors, i.e., substances which prevent the deposition of fat in, or accelerate its disappearance from the liver. Large fatty livers were found in depancreatized dogs maintained on a mixed diet and insulin, which could be prevented by the addition of fresh beef pancreas. Hershey and Soskins³² found that lecithin contained the same lipotropic activity and it was then demonstrated that choline was the active component of this phospholipid.^{33 34} Subsequently the lipotropic activity of choline, when added to diets of rats in whom cirrhosis had been produced, was shown by several investigators.^{11 35 36 37}

The first evidence that protein affected the deposition of fat in the liver was obtained by Best and Huntsman.³⁶ They found that the addition of casein to a deficient diet reduced the amount of fat in the liver. It was thought that the lipotropic action of casein was not due to the negligible amount of choline it contained. It was suggested that its action might be through the methionine which possesses labile methyl groups which may be the determining factor in lipotropic activity.³⁷

Elman and Heifetz³⁸ have demonstrated definite impairment of the liver function in protein depleted animals, and conversely, it has been shown that dietary protein may protect the liver against the effects of exogenous toxins.^{39 40 41} Fagin, Sahyun and Pagel⁴² analyzed the liver specimens from alcoholic patients with cirrhosis of the liver for their total lipid and nitrogen content. They found that specimens from patients who had received a fortified casein hydrolysate as part of their therapy contained a greater percentage of protein and a lesser percentage of fat than specimens from patients who had not received casein hydrolysate.

DIETARY TREATMENT

Patek¹⁹ and Patek and Post⁴³ reported on a series of fifty-four patients with cirrhosis of the liver who were given a diet rich in protein and ample in carbohydrate and fat. The diet contained protein 139 gm., fat 175 gm. and carbohydrate 365 gm., furnishing 3591 calories. The diet consisted chiefly of meat, milk, eggs, fruit and green vege-

tables, and was supplemented with 50 gm of brewers' yeast daily. In addition, thiamine hydrochloride 5 mg was injected daily and liver extract 5 cc twice weekly. Of the fifty-four patients on this regimen, twenty-two showed signs of progressive failure, twelve made partial improvement, and the remainder showed signs of "clinical recovery."

In comparison with a control group, the period of survival of these patients showed the following differences. At six months, 57 per cent of the controls were alive in contrast to 72 per cent of the treated series, at one year 39 per cent of the controls and 57 per cent of the treated series, at two years 22 per cent of the controls and 45 per cent of the treated series. In addition to the increased period of survival there were signs of general bodily improvement, disappearance of ascites, edema, jaundice and vascular spiders, together with improvement in certain laboratory tests.

Fleming and Snell⁴⁴ also reported significant clinical improvement in 44 per cent of a group of patients receiving a high protein, high carbohydrate diet supplemented with large doses of vitamins, as compared with satisfactory results in 31 per cent of patients receiving a high carbohydrate diet and diuretic agents.

USE OF LIPOTROPIC FACTORS

Broun and Muether⁴⁵ reported a good response by patients with hepatic cirrhosis to the administration of choline chloride, 1 gm daily plus a low fat, high protein diet. On the other hand, Yater⁴⁶ in a study of fifteen patients, does not think that choline is effective in treatment of cirrhosis. In addition to a high protein, high carbohydrate, low fat and high vitamin diet (protein 215 to 150 gm, fat 50 to 60 gm, carbohydrate 300 gm) Russakoff and Blumberg⁴⁷ administered choline chloride orally in doses of 2 gm three times daily. Seven of the nine patients so treated showed definite clinical improvement with reduction in the size of the liver, great diminution or disappearance of ascites, increase in the serum albumin, improvement of the hemogram, decrease of the prothrombin time and normal liver function tests. Two patients, one with an enlarged fibrotic but nonfatty liver and one with a small shrunken liver, failed to improve. In a series of unreported cases at Bellevue Hospital, the administration of raw pancreas, and large doses of casein and choline either alone or in combination, failed to influence the course of the hepatic cirrhosis. However, the poor results may well have been due to the short period of treatment of these patients.

Beattie and Marshall⁴⁸ obtained considerable success in preventing and treating liver damage due to widely differing causes by the administration of methionine or by the use of casein digests with the methionine.

GENERAL COMMENT

The nutritional treatment of cirrhosis of the liver implies intelligent, patient nursing care. Most cirrhotics have poor appetites and an aversion for food, making the consumption of a full diet a real problem. The presence of ascites increases discomfort and adds to the difficulty of eating because of mechanical interference with the gastrointestinal tract. For this reason it may be advisable to reduce the amount of ascitic fluid present, either by diuretics or by abdominal paracentesis.

On the Medical Service of the Psychiatric Division of Bellevue Hospital,⁴⁰ it was found that the cause of death of patients with cirrhosis of the liver, who succumbed within the first ten days after admission, was, as a rule, not due to progressive liver failure per se, but rather either to infection or to one of the encephalopathic states. Jolliffe and Worts²¹ have pointed out the probable avitaminotic etiology of these syndromes. It may be necessary, therefore, to institute immediate parenteral vitamin therapy in large doses to prevent rapid death in the encephalopathic state, before caring for the underlying cirrhosis. Specifically, the diet should be high caloric, high vitamin and high protein. With patient effort many patients with cirrhosis can be coaxed to eat 140 gm. of protein, though in many patients, 100 gm. seems to represent the upper limit of tolerance.

In addition to the large amounts of protein in the diet, we have been impressed recently with the seemingly better results obtained by supplementing the diet with large amounts of a fortified casein hydrolysate so that the nitrogen intake is made to approach 0.6 gm. of nitrogen per kilogram of body weight. This diet then should be supplemented by a source of the natural B-complex such as brewers' yeast or its extracts. If this causes too much stress on the gastrointestinal tract we administer a crude liver extract (5 cc.) by intramuscular injection. For vitamin supplementation we have preferred a formula containing thiamine 10 mg., riboflavin 5 mg., niacinamide 50 mg., and ascorbic acid 100 mg. In addition vitamin A in 50,000 units twice daily is given and, when indicated, one of the preparations of vitamin K. On this basic nutritional therapy of the cirrhotic, other therapy is instituted.

SUMMARY

1. On the basis of experimental and clinical evidence, it is possible to postulate that the liver made more vulnerable by an unfavorable nutritional environment, reacts to a variety of toxins causing parenchymal damage by the deposition of excess amounts of neutral fat which may go on to progressive fibrosis and atrophy.

2. Favorable results in treatment have been obtained by the use of a high protein, high carbohydrate, moderate to low fat diet, plus fortified casein hydrolysate, dried brewers' yeast by mouth, liver extract parenterally and administration of specific vitamins when indicated.

3 The lipotropic factors—casein, choline and methionine—either alone or in combination, may be used experimentally

LYMPHOGRANULOMA VENEREUM

ROBERT B GREENBLATT, MD * AND PAUL L WERMER, MD †

CONTRARY to popular opinion, lymphogranuloma venereum is apparently an ancient disease since Greek, Roman, Hebrew and Arabian physicians carefully described draining buboes which coincide closely with our conception of the inguinal syndrome.¹ During the Dark Ages this knowledge was lost. In the great pandemic of syphilis during the sixteenth century, these buboes were again described, but attributed to syphilis. The failure of the buboes to respond to mercurial therapy aroused the suspicion of early English and French authorities that they might not be syphilitic.^{2,3} In the latter half of the 19th century the relationship of anorectal syndrome and elephantiasis was described.⁴ It remained for investigators of this century, especially in the last three decades, to gather together the various conditions named climatic or tropical bubo strumous or scrofulous bubo, lymphogranuloma inguinale, paradenitis, lymphopathia venereum, lupus vulvae, the fourth venereal disease, the sixth venereal disease, Nicolas-Favre disease, and prove that they were but manifestations of the same disease. The venereal origin of lymphogranuloma venereum was demonstrated for the first time during this period.^{5,6}

This tremendous volume of investigation and interest in lymphogranuloma venereum has resulted in the development of methods which definitely place this disease within the ability of the family physician to diagnose and treat in his own office. It is important that the general practitioner recognize this, since he is the first to be consulted by the patient and upon his early diagnosis and proper institution of therapy, distressing late manifestations of lymphogranuloma venereum may be avoided.

DEFINITION

Lymphogranuloma venereum is a systemic disease acquired venereally, the causative agent of which is filtrable. It is characterized by the appearance of a small, evanescent, often unnoticed primary lesion of the genitalia or other mucosal surface, followed by a secondary spread of the infection along the lymph channels and nodes draining the area,

* Surgeon (R) United States Public Health Service, United States Coast Guard Yard Curtis Bay Maryland (Now on active sea duty with the Coast Guard.)

† Surgeon (R) United States Public Health Service, Medical Center Hot Springs, Arkansas (Now Director of the Venereal Disease Clinics, Chicago Health Department.)

with resultant subacute lymphadenitis and/or a chronic, neoformative, inflammatory reaction of the subjacent connective tissues of the invaded parts ⁷

ETIOLOGY

The specific causative agent of lymphogranuloma venereum is filtrable and probably belongs to a class of pathogenic entities between the virus and rickettsia.^{8,9} Experimental animals and the yolk cells of the developing chick embryo have been successfully inoculated with the agent and the disease transmitted back to man to satisfy Koch's postulates ^{10,11,12 18} Early observers noted inclusion or Gamma bodies (0.7 to 4.0 μ) in the cytoplasm of mononuclear cells in lymph nodes of both the human and experimental disease ^{10,11 12} Further investigation has disclosed a probable developmental cycle during the greater part of which the agent may be seen microscopically under oil immersion ^{14,15} The *elementary or inclusion body* (0.1 to 0.175 μ) is apparently the invasive form, and must enter a living cell to continue development After penetration into the cell, these forms disappear, and no type of organism is demonstrable It is postulated that during this period the agent becomes ultramicroscopic In ten to twelve hours after inoculation, the *agent or initial body* (0.4 to 0.7 μ), more than double the size of the inclusion body, may be seen in the cytoplasm of the invaded cells The agent bodies reproduce by fission to produce plaques enclosed in cysts within the cytoplasm The plaques then vacuolate and break up into individual forms resembling the original inclusion body This is followed by rupture of the cyst wall and cell membrane and release of the newly formed inclusion bodies to invade neighboring cells of the host tissue ^{13,14 15 15a}

A toxin is elaborated by the agent, probably accounting for the severe systemic reactions encountered occasionally in the human disease ¹⁵ The agent definitely produces an immunologic response in its host as demonstrated by the complement fixation test, Frei test, and use of convalescent serum in treatment. The filtrable agents of psittacosis, trachoma, inclusion blennorrhoea, human atypical pneumonia, acute meningopneumonitis, and mouse pneumonitis are closely related to the agent of lymphogranuloma venereum ^{15a}

INCUBATION PERIOD

The primary lesion develops within five to twenty-one days after exposure, the average being seven to twelve days However, since the primary lesion is so transient, it often escapes notice, and the bubo may represent the first manifestation noted by the patient The bubo usually appears ten to thirty days after the exposure, but at times months may elapse before its appearance ¹⁶

EPIDEMIOLOGY

The disease is contracted and spread primarily by sexual intercourse and perversities. Accidental infection also plays a role, especially in the extragenital forms of the disease. Lymphogranuloma venereum is met with most frequency in tropical and semitropical countries, but has spread along the lines of commerce throughout the world, appearing especially along sea coasts¹⁷

INCIDENCE

Age—The greatest number of cases occur during the period of greatest sexual activity. Children have been infected accidentally by exposure to the agent in contaminated clothing, douche nozzles and sinus discharges¹⁸. Whether there can be placental transmission of the disease is a moot question in the human host. Abortion is a frequent concomitant to lymphogranuloma venereum infection occurring early in gestation. Experimentally, the agent has been transmitted into the fetus of the infected mouse, by way of the placenta. One of us (R B G) has skin tested some fifteen infants and children of mothers known to have active lymphogranuloma venereum during gestation without encountering a single positive Frei reaction. Other investigators have found positive Frei reactions in similar cases¹⁹.

TABLE 1 —RATE OF ADMISSIONS FOR LYMPHOGRANULOMA VENEREUM PER 1000 MEAN STRENGTH, U S ARMY AND U S NAVY

Year	Army	Navy
1936	0.1	0.82
1937	0.4	1.10
1938	0.5	1.87
1939	0.4	2.11
1940	0.5	1.54

Data from Annual Reports of the Surgeon General U S Army 1937-41 Statistics of Diseases and Injuries.

Race—All races exposed to the disease are susceptible. In the University of Georgia Clinics, a series of 197 cases showed but thirteen white infections to 184 colored, a ratio of 1:16. Other observers also report high incidence in the negro race^{20, 21, 22}.

Occupation—In keeping with the preponderance of cases along the sea coasts, sailors contract the disease with comparative frequency. In Army and Navy statistics this is startlingly apparent, the Navy rates per 1000 men being three times as high as the Army rates (Table I). In females the prostitute class shows the highest incidence of infection.

Sex—The reported sex incidence seems to favor the male, but this probably is more apparent than real. Poor reporting and nonrecog-

nition of the disease make any statistics on incidence extremely vulnerable to error. In the University of Georgia Clinics greater incidence has been observed in the female (Table 2). The epidemiology of the disease itself should argue against a differential sex ratio.

TABLE 2—AGE AND SEX INCIDENCE OF LYMPHOGRANULOMA VENEREUM IN 197 CONSECUTIVE CASES AT THE UNIVERSITY OF GEORGIA CLINICS

Age	Male	Female	Age	Male	Female
0-10	0	2	41-50	5	9
11-20	19	16	51-60	1	4
21-30	44	59	Total	79	118
31-40	10	28			

INFECTIOUSNESS AND PERIOD OF COMMUNICABILITY

The disease must be considered infectious while an open lesion or discharge from any source is present. Even chance contact of a mucosal surface with a contaminated article is sufficient to infect. This has been demonstrated experimentally by insertion of a contaminated enema tip into the lower bowel of the chimpanzee with resultant infection.²³ Sexual exposure to an open case almost inevitably is followed by infection. Even in the face of clinical recovery, the agent has been demonstrated to persist for twenty-one years and retain its infectiousness.²⁴ In the absence of open lesions the vaginal secretions have been shown to be infective.^{25, 26} It is reported that practically the entire population of a Greek island was infected following the introduction of the disease by a single, infected prostitute.²⁷

CONTROL

In considering incidence and control of lymphogranuloma venereum, it is particularly unfortunate that the disease is not on the list of communicable diseases for which notification is required by the states.²⁸ No accurate estimation of incidence or adequate epidemiologic investigation is possible under these circumstances. In 3000 admissions to the United States Public Health Service Medical Center in Hot Springs, Arkansas, between 1937-9, forty-nine cases of lymphogranuloma venereum were found, an incidence of 1.6 per cent.²² This report is felt to be lower than actual incidence in this group since routine Frei tests were not performed and the etiology of rectal stricture not fully investigated during this period. Furthermore, it represents incidence not in the general population, but in a sexually promiscuous class with an extremely high index of venereal infection.

CLINICAL ASPECTS

Location and Character of Primary Lesion—The most common site of the primary lesion in the male is the coronal sulcus, followed by the

prepuce, glans, shaft and urethra. The most common sites in the female are the posterior vaginal wall and the region about the fourchette,²⁰ although it may appear on any part of the external genitalia. The inoculatory lesion may be either (a) a small erosion, (b) an infiltrated papule, (c) a herpetiform vesicle or ulcer.

The ulcer is small and shallow with ill defined edges, the base whitish gray, it is painless and often surrounded by an area of erythema. The lesion is soft on palpation, not infiltrated. It heals spontaneously in three to five days.^{29 30 31 32} Its location, painlessness and transitory, evanescent nature often cause the primary lesion to be overlooked by the patient. Very often, after the disappearance of the primary lesion and coincident with the inguinal bubo, a secondary ulceration appears on the genitalia which is often mistakenly considered as the primary lesion (Fig 134)

Fig 134—Evanescent primary lesion (A) of lymphogranuloma venereum which was followed in three weeks by an ulceration of the shaft of the penis simultaneous with bilateral buboes (B)

Symptomatology—The lymph drainage area of the primary lesion is the determining factor in the progress of lymphogranuloma venereum. The course may be acute, subacute, chronic or latent. Exacerbations and remissions may occur. Lymphogranuloma venereum is a systemic disease and severe constitutional symptoms may be present during the early, insidious spread to the regional lymphatics. Fever, chills, sweats, joint pains, vague abdominal aches, anorexia and occasionally meningism or a typhoidal state may occur.^{30 33} Recently several cases of meningoencephalitis have been reported.³⁴ A fleeting arthritis is said to occur in 10 per cent of the cases which have persisted over a period of several months.¹⁷

Clinical Varieties.—Both genital and extragenital varieties of the disease occur.

I GENITAL VARIETIES

(A) *Inguinal Syndrome*—Ten to thirty days after the inoculatory exposure, one or more discrete, movable, tender nodes may be felt in the inguinal region (Fig 135) The inflammatory process may progress for several days and then spontaneously regress in 20 to 25 per cent of the cases³⁶ Usually the process continues to spread, involving all the nodes in the group and extending to the surrounding connective tissue to set up a periadenitis The buboes become quite noticeable, bulging out the skin paralleling the inguinal groove The mass of nodes may be lobulated, oval or markedly elongated, and sausage-shaped The skin becomes adherent and often takes on a violaceous hue

The Sign of the Groove—Enlargement of nodes above and below the inguinal fold produces a distinct groove (Fig 136) which is almost pathognomonic of lymphogranuloma venereum³⁶ The buboes may

Fig 135—Inguinal buboes—upper right about to rupture, lower, draining

remain indurated and nodular for many months, or irregular areas of softening occur, succeeded by formation of multiple fistulas draining a grayish, thin pus Occasionally the suppuration results in a unilocular abscess Inguinal adenopathy is generally unilateral, but is bilateral in about a third of the cases It occurs with more frequency in the male¹⁷ This variation is due to the difference in lymphatic drainage of the sexes Lymph drainage of the penis is to the inguinal and iliac nodes^{30 37} In the female only the clitoris, urethra and anterior part of the vulva are drained by these nodes, thus only primary lesions of these areas can produce the inguinal syndrome in the female Nevertheless it occurs with more frequency in females than commonly reported In the University of Georgia clinics ninety-six cases of lymphogranuloma venereum in the female were reviewed, of these patients twenty-nine had buboes at admission and four had a history of buboes—an incidence of 34.3 per cent¹⁶ In seventy-seven male pa-

tients the syndrome occurred fifty-six times, an incidence of 72.7 per cent. Healing is accompanied by scarring, wrinkling and dimpling of

Fig 136—Sign of the groove.

Fig 137—Bubonuli, small abscesses along the course of the lymphatics of the penis.

the skin about the sinus opening.²⁸ Constitutional symptoms often occur early in the inguinal syndrome.

(B) **Genital Syndrome**—After disappearance of the primary lesion, massive multiple ulcerations of the penis or vulva may develop. Hypertrophy and hyperplasia of the tegument and underlying connective tissue due to local lymph stasis and dilatation of lymph channels may follow. In the male, *bubonuli*, small abscesses along the shaft of the penis following the course of the lymphatic channels (Fig 137), occasionally occur. With sufficient lymph stasis, massive elephantiasis of the penis may ensue. In the female, elephantiasis occurs with more frequency than in the male. Elephantiasis, with ulcerations of the vulva and perianal region, constitute the syndrome called *esthiomene* (Fig 138). The enlargement may affect any or all parts of the external genitalia. On palpation the parts are turgid, and rubberlike in consistency, due to the chronic, inflammatory, neoformative reaction. The ele-

Fig 138—*Esthiomene*—elephantiasis and ulceration of the vulva and lobulated anal growths

phantiasic surfaces may be smooth, verrucose or corrugated with a "cobblestone-like" appearance (Fig 139). Pedunculation of the elephantiasic labium and clitoris are quite frequent (Fig 140). The ulcerative lesions have a pearly, translucent, granulomatous base with uneven projecting tufts of granulation tissue. The ulcers may involve the vaginal mucosa and progress to form rectovaginal fistulas. On healing, cicatricial contracture may cause vaginal stricture.

(C) **Anal Syndrome**—Polypoidal and lobulated growths about the anal orifice occur either alone or accompanying the genital or rectal syndrome. In the early stages of this syndrome, indurated rubbery anal tabs of opalescent hue are present and may be mistaken for hemorrhoids (Fig 141). The term "lymphorrhoids" has been suggested and seems apt and descriptive for these lobulated anal tabs caused by

Fig 139—Elephantiasis of clitoris, labia majora and rectal stricture. Note cobblestone appearance of granulation tissue.

Fig 140—Genito-anorectal syndrome. Note marked elephantiasis of clitoris and labia, lymphorroids. This patient also had rectal stricture.

lymph stasis. The anorectal syphilomas described by Fournier in 1875 were in all probability the lymphorrhoids of the anal syndrome.⁷

(D) **Rectal Syndrome**—In the male, this syndrome follows primary infection of the rectal mucosa, most usually acquired as a result of sodomy^{39, 40} Its appearance requires careful and judicious approach to the possibility of irregular sex practice At the United States Public Health Service Medical Center, one recent instance of rectal stricture in the male was acquired while the victim was serving a sentence in the penitentiary of a nearby state This patient claimed that sodomy was practiced upon all new inmates by gangs of fellow prisoners

Fig 141—Lymphorrhoids—hemorrhoid-like anal tabs caused by dilatation of anal lymphatic channels

In the female, the rectal syndrome is much more common, and while it may occur as a result of sodomy, it most usually occurs as a result of primary infection of the vagina, or of the posterior two thirds of the vulva The lymph drainage of these areas is to the para-rectal glands^{30, 37} In children and adults the syndrome has followed the use of an infected enema tip¹⁷ Proctitis is indicative of a primary locus of infection in the rectal mucosa, its absence indicates the infection began outside the rectal wall⁴¹ This finding may be utilized to classify the rectal syndrome into its various components

Primary in Rectal Mucosa*

- 1 Proctitis
- 2 Proctitis with rectal stricture

Primary Outside Rectal Mucosa

- 1 Rectal Stricture
- 2 Rectal Stricture with abscess formation

* Most male cases in this group

INFECTION ORIGINATING IN RECTAL MUCOSA

1 *Proctitis*—This condition usually begins with small rectal hemorrhages. Proctorrhea with a purulent discharge is found in practically every case.⁴² The discharge is the most annoying symptom, since *pain is very seldom experienced*. The proctoscopic examination may reveal an edematous, boggy, redundant mucosa, or a granulomatous, ulcerative lesion, or polypoid verrucous hypertrophy of the mucosa. Residual polypoid growths may persist long after the infection apparently has resolved. Therefore, rectal growths which prove not to be neoplastic on histopathologic study, should be restudied with lymphogranuloma venereum in mind as a causative agency.⁴³

2 *Proctitis with Rectal Stricture*—If untreated, the proctitis progresses, burrowing deeper into the bowel wall to encircle the entire lumen. When healing ensues, cicatricial contraction of the scar tissue gradually obliterates the lumen.

INFECTION ORIGINATING OUTSIDE RECTAL MUCOSA

1 *Rectal Stricture*—This condition may be found without any other manifestation of lymphogranuloma venereum and often in the absence of any history of a primary lesion or bubo. The pararectal nodes are the site of secondary involvement from the usual genital, primary lesion. They may be seen at laparotomy as groups of pearly, bean-shaped nodes studding the bowel wall. Retrograde extension of the infection along the lymphatic channels involves the outer coats of the bowel. Subsequent lymph stasis, edema and ultimate organization produces rectal stricture by cicatrization with gradual, progressive reduction of the lumen of the gut.

2 *Rectal Stricture with Abscess Formation*—Untreated, the infection of the pararectal nodes and the perirectal tissues progresses, as in the inguinal syndrome, to abscess formation. Unlike the inguinal glands, the pararectal glands lie deep in the tissues and have no easy means of evacuation. The multiple abscesses produced, burrow in many directions through the perirectal-vaginal tissues, to produce sinus tracts and fistulous openings in the vagina, rectum, ischio-rectal and perianal areas. The fistulas always originate below the stricture, and their association with the pararectal glands, has been demonstrated by injection with iodized oil and radiography.^{37 44} The infection may run its course and healing take place. Usually it persists, running a chronic course with widespread diffusion of the process throughout the pelvic lymph spaces, channels and lymph nodes. The rectum, vagina, uterus

and adnexa may be fixed and a "frozen pelvis" ensue. The lymphangitis and lymphadenitis with blockage of lymph drainage may result in other syndromes presenting themselves, i.e., elephantiasis, stricture of the urethra and vagina.

RECTAL STRICTURE—SPECIAL CONSIDERATIONS—The rectal stricture of lymphogranuloma venereum is of a cylindric, constricted "rubber hose" variety. It is usually situated 3 to 8 cm above the anal sphincter. Its average length is 4 cm, although strictures involving the whole rectum and the colon have been reported.²⁸ Early, the walls have an "india-rubber" consistency, later, more induration follows until the wall becomes semi-rigid as fibrous tissue replaces the edematous and indurated tissue. Untreated strictures are progressive, the lumen may become so constricted that ileostomy or colostomy must be performed. Pain is a symptom of primary importance in cases of proctitis, since its appearance probably marks the beginning of stricture formation. Constipation parallels the degree of stricture, the stools become more ribbon-like with the stricture progression, abdominal cramps and tenesmus develop with the restriction of fecal passage. The progress of the constriction is slow¹⁷ and is a late manifestation when proctitis is absent.⁴² When proctitis is present, strictures have been reported to begin within three months of the onset of proctorrhea.¹⁷

Other portions of the gastrointestinal tract may be involved by lymphogranuloma venereum. One recent report of a series of cases describes inflammatory lesions of the cecum and colon, enlarged mesenteric lymph nodes, multiple hepatic abscesses, sterile fibrinous peritonitis and perforation of an ulcer of the colon.⁴⁵

Ulcerative colitis, with typical bloody rectal discharges, has been reported. The lesions start in the rectum and usually remain confined to the distal segments of the large intestine. Rectal stricture and multiple small sinuses proceeding from the mucous membrane to the deeper structures are often concomitant findings.⁴⁶

Rectal Stricture and Pregnancy—While rectal stricture is not necessarily a contraindication to vaginal delivery, its presence associated with perirectal fibrosis, soft tissue masses or fixation of the posterior vaginal wall may lead to rupture of the uterus. Intraperitoneal rupture of the rectum has also occurred in attempted breech extractions when the aftercoming head passed over the stricture.^{46, 47}

(E) Urethral Syndrome—The first symptom is a purulent discharge containing many polymorphonuclear cells but no visible pathogenic organisms. All cases of "nonspecific" urethritis, with a history of sexual exposure shortly before the symptomatology develops, should have repeated Frei tests to eliminate the possibility of lymphogranuloma venereum as a causative agency. Urethral strictures, ulcers and fistulas may supervene. Acute and chronic prostatitis, seminal vesiculitis and epididymitis may occur in the male. In the female, esthiomene often is associated with bladder neck deformation and late in the course of the

disease involvement of the perirectal and parametrial tissues, and the deep nodes may cause displacement, compression or invasion of the genitourinary structures ^{47a}

II EXTRAGENITAL LYMPHOGRANULOMA VENEREUM

Apparently any mucous membrane exposed to the agent of lymphogranuloma venereum may become the site of the primary lesion. The secondary manifestations will develop in the lymph drainage area of the initial locus, because of the lymphotropism of the disease. Various perverted sexual practices have led to infections of the tongue, ⁴⁸ tonsil, ⁴⁹ mucous membrane of the mouth, the hypopharynx, larynx⁵⁰ and the conjunctiva (Parinaud's conjunctivitis) ^{51, 52} Axillary buboes have developed following accidental inoculation of the finger during opera-

TABLE 3 —FREQUENCY OF CLINICAL MANIFESTATIONS OF
LYMPHOGRANULOMA VENEREUM

Type of Disease	New York Hospital		University of Georgia Hospital Clinics	
	No of Cases	Per Cent	No of Cases	Per Cent
Anorectal	145	59.9	46	30.7
Inguinal	60	24.8	77	51.3
Genital	28	11.7	26	17.3
Asymptomatic	6	2.5		
Urethral			1	0.7
Miscellaneous*	3	1.1		

* Includes one case each of carcinoma of rectum, cystitis and granulomatous pelvic masses (Courtesy of E. R. Squibb & Sons, Monograph Lymphogranuloma Venereum)

tive procedures ^{50 53 54} Laboratory workers handling high concentrations of the agent have developed generalized symptoms, septic type fever with chills, sweats, joint pains and headache ⁵⁵ Cervical adenitis is occasionally a concomitant of these cases Meningeal infections have been reported ^{54 56, 57}

It should be emphasized that, while syndromes have been presented as separate entities, clinically they may occur separately or in any combination

CLINICAL COURSE

The variants of host susceptibility and agent virulence lead to wide latitude in clinical course. The disease may be so minimal in some that the patient is never aware of the infection In others the disease may be so chronic as to persist for years, with residual lesions so incapacitating and debilitating as to make the patient a possible public charge

Fig 142 —Marked elephantiasis and pedunculation of labia minora, labia majora and clitoris

Fig 143 —Genital syndrome—elephantiasis of penis and scrotum, draining sinuses of scrotum

In one patient a syndrome may progress with great rapidity, in another, with indolence, and in a third it may remit spontaneously. The

female patient, because of her lymphatic drainage, may present simultaneously, or successively, various syndromes. The fibroblastogenic diathesis of the Negro frequently results in marked neoformative reaction of the tegument and underlying connective tissue to the agent of lymphogranuloma venereum, with formation of gargantuan hypertrophy and elephantiasis (Fig 142) ⁵⁸ In the white race, elephantiasis is a rare condition. Since lymphogranuloma venereum is a subacute inflammatory process causing hypertrophy and neoplasia, malignancy may supervene. Anaplasia and metaplasia occur with more frequency than in the other granulomatous processes ^{59 60 61}

DIAGNOSIS

1 **History**—If obtainable, the history of an evanescent, herpetiform lesion followed by the development of signs and symptoms suggestive of one of the syndromes of lymphogranuloma venereum is a most valuable adjunct to diagnosis.

2 **Clinical Picture**—A subacute, inflammatory neoformative, granulomatous process, or "sign of the groove" enlargement of regional lymph node or elephantiasic lesions or fistulous tracts discharging gravish pus, suggest lymphogranuloma venereum.

3 **The Frei Test** ⁶²—This intradermal test represents the most important single aid to diagnosis. It usually becomes positive by the time of bubo formation (ten to thirty days after infection). Originally human bubo pus was sterilized and diluted to produce an antigen. This method had the disadvantage of the lack of a control to eliminate non-specific reactions. Later a mouse brain antigen was devised which provided an unlimited supply of test material and had the advantage of a control ^{62, 63 64}. The disadvantages of mouse brain antigen were non-specific reactions, low concentration of the agent and the possibility of sensitizing the patient to the antigen ^{65 66 67}. Recently an antigen has been perfected from the infected yolk cells of the chick embryo ^{68 69}. This preparation yields high concentrations of antigen, has an available control material and elicits the least number of false positive reactions ^{17 21 62 63 64, 65 70 71 72 73 74}. The test is performed by the intradermal injection into the forearm of 0.1 cc. of the antigen and 0.1 cc. of the control. The test should be read at forty-eight hours and preferably again at seventy-two hours. In reading the test, erythema or flare should be disregarded. A positive test is indicated by an indurated, inflammatory nodule measuring at least 5 to 6 mm along its greatest diameter. Mensuration should be done with an accurate millimeter scale from the margin of *beginning induration* to the *end of the induration*. Positive tests tend to persist for many days, while false positives tend to disappear within seventy-two hours ⁷⁰. A negative test, in what seems a typical case, may be due to anergy ⁵⁷ or the test may have been performed too early in the disease. The area tested should be observed for a week, as late or delayed reactions sometimes

occur and if still negative, repeat the test. Necrosis, or the development of a bleb or vesicle in the center of the nodule, indicates a highly positive reaction. The control reaction should not exceed 3 mm. A positive test may be reversed by intensive, early, sulfonamide therapy,⁵⁵ but in well developed or chronic cases the test remains positive for life. In extreme debility or the moribund state, anergy may result.³⁶

4 Biopsy—The histopathologic picture of lymphogranuloma venereum is highly suggestive of the diagnosis, but not specific. In doubtful cases, where multiplicity of infections may be present, it is of considerable value. In the bubo form, inflammatory and suppurative changes are found in the lymph nodes and perilymphoid tissues. There is a combined polymorphonuclear and granulomatous reaction characterized by minute foci of necrosis or micro-abscesses surrounded by macrophages and an occasional giant cell. In elephantiasis, there is pronounced peritubular infiltration with plasma cells and lymphocytes, accompanied by fibroblastic activity, dilated lymphatics, in some cases with giant cells of foreign body type and foci of suppuration similar to those encountered in buboes.^{61, 75} In the benign neoplastic form of lymphogranuloma venereum, biopsy is a great aid in ruling out malignancy.

5 Autoinoculation—Bubo pus removed by aspiration under sterile precautions rubbed into a scarified area of the thigh *will not* produce ulceration in lymphogranuloma venereum, while in chancroid disease it frequently will produce a characteristic chancroidal ulcer.³⁶

6 Complement Fixation Test^{76 77 78}—Judiciously utilized, the complement fixation test is considered to have value in early diagnosis. A concentrated, purified chick-embryo antigen is now available commercially for complement fixation. Unfortunately, cross reactions occur with syphilis and members of the psittacosis-lymphogranuloma venereum group.^{79, 80 81} The complement fixation test becomes positive earlier than the intradermal test. When repeated Frei tests result in doubtful reactions, a test of high titer dilution (1-80 or higher) is suggestive of lymphogranuloma venereum. Titers below 1-80 must be regarded with doubt. Therapy apparently lowers the titer, but does not change the positive complement fixation reaction. Greater specificity is necessary before major reliance may be placed on this test.

7 Inverted Frei Test⁸²—In certain instances a negative Frei test is obtained even in the presence of a suppurative bubo. The pus aspirated from a bubo, macerated and ground up lymph nodes or infected tissue may be made into an antigen and injected into known cases of lymphogranuloma venereum, particularly persons with rectal stricture. Incontestable positive reactions in persons with proved lymphogranuloma venereum and absolutely negative reactions in normal controls and in persons with allergy to chancroid must be obtained, if the inverted Frei test be accepted as of diagnostic significance.

Preparation of Frei Antigen From Bubo Pus—The fluctuant bubo is aspirated under sterile conditions using a 16-gauge needle. The surface of the bubo is first prepared by shaving and cleaning with skin disinfectants such as alcohol and ether or iodine. Patients with positive blood serologic tests for syphilis, positive chancroid skin test, or fistulization of the bubo should not be used. Spreads and routine cultures of the aspirated pus are made to rule out the presence of bacteria.

The pus is diluted with 4 parts of sterile normal saline solution as soon as possible after aspiration. The diluted material is immersed in a water bath of 58 to 60 degrees C. for two hours and on the next day for one hour. Further tests for sterility by spread and culture are made. If all bacteriologic tests are negative, phenol (0.25 to 0.5%) is added to the antigen as a preservative.

8 Blood Chemistry—The blood picture is not characteristic, moderate secondary anemia has been reported and the sedimentation rate is increased.^{83 84} Blood chemistry presents one test of occasional value in early diagnosis—the increase in serum proteins, especially globulin (up to 9 per cent).^{87 88 83 80 87 88 80} Granuloma inguinale and other chronic diseases cause marked change in the serum globulin content and reduce the value of this finding.^{84 88}

DIFFERENTIAL DIAGNOSIS

Syphilis—Syphilis may imitate the primary and secondary ulcers of lymphogranuloma venereum, the buboes of the inguinal syndrome and the urethral syndrome. To further complicate the situation many coincidental infections of these two conditions exist. Darkfield examination with identification of the *Treponema pallidum*, or a positive serologic test, establishes the diagnosis of syphilis but does not rule out the possibility of coexistent lymphogranuloma venereum. This is especially true in the face of a positive Frei test, and of lesions and buboes that persist despite antisypilitic therapy. Repeated negative darkfield examinations of ulcers and of node puncture material as well as repeated negative serologic tests for syphilis rule out this diagnosis.

Gonorrhea—The urethral discharge, cutaneous ulcers⁹⁰ and proctitis of gonorrhea must be differentiated from lymphogranuloma venereum. The Frei test very often is not positive for some time after the onset of the urethral discharge in the urethral syndrome. Repeated negative cultures (five or more) and negative spreads for the gonococcus must be obtained before ruling out this diagnosis. A positive Frei and a positive complement fixation test validate the lymphogranuloma venereum diagnosis and eliminate *nonspecific urethritis*.

Chancroid—The ulcerative lesion and bubo of chancroid may be differentiated from lymphogranuloma venereum by the autoinoculability of chancroid and by demonstration of the Ducrey bacillus. The positive Frei and complement fixation tests are aids in establishing the diagnosis of lymphogranuloma venereum. The skin test for chancroid and the Frei test often show simultaneous reactions when only one of the diseases is clinically present.^{91 92} These are not necessarily to be considered as false positives, since the test may represent previous in-

fection⁹³ If only one skin test is positive, then it serves to differentiate between the diseases The ulcers of lymphogranuloma venereum are usually painless, if uncomplicated, while those of chancroid are often painful, phagedenic, and acutely inflamed

Granuloma Inguinale—The positive Frei test, positive complement fixation test, as well as the failure to demonstrate Donovan bodies in biopsy or scrapings after repeated trials, establish the diagnosis of lymphogranuloma venereum The inguinal swelling encountered in granuloma inguinale is actually a subcutaneous, granulomatous process, individual nodes cannot be differentiated in this mass Both entities may, and frequently do, occur together Secondary elephantiasis, indurative in type, is not uncommon in granuloma inguinale

TABLE 4—VARIOUS CONDITIONS FROM WHICH THE SYNDROMES OF LYMPHOGRANULOMA VENEREUM MUST BE DIFFERENTIATED

Ulcers, Primary and Secondary	Inguinal Syndrome	Anorectal Syndrome	Genital Syndrome	Urethral Syndrome
Syphilis	Syphilis	Malignancy	Filariasis	Gonorrhea
Herpes progenitalis	Granuloma inguinale	Hemorrhoids	Kraurosis	Intraurethral chancre
Chancroid	Tuberculosis	Gonococcal proctitis	Fibroma	Nonspecific urethritis
Granuloma inguinale	Chancroid	Rectal schistosomiasis	Malignancy	
Gonorrhea	Hodgkin's disease	Polyposis	Urogenital schistosomiasis	
Fusospirochetosis	Tularemia			
Malignancy	Actinomycosis			
	Regional adenitis			

Herpes Progenitalis—This eruption is usually preceded by a prodromal itching and a sensation of heat, rarely by pain This is followed by the appearance of single or multiple pinhead-sized vesicles which rupture and occasionally coalesce to form a superficial lesion with shaggy, irregular edges Occasionally enlarged, tender nodes are found which may reach bubo proportions The history of previous crops of herpetic vesicles may be obtained in most instances The Frei test and positive complement fixation test establish the diagnosis of lymphogranuloma venereum

Fusospirochetosis—In primary fusospirochetosis the early lesions have a moist, pinkish, glazed appearance When ulceration gets under way it is rapid and destructive The spirillum and vibrio of Vincent may be demonstrated readily in spreads stained with Wright's stain or by darkfield examination Primary fusospirochetosis may be responsible for an erosive and gangrenous balanitis and may resemble a phage-

denic, chancroidal infection. Genital lesions frequently become contaminated with fusospirochetes, and occasionally these saprophytic organisms play a role in the destructive or recalcitrant nature of the underlying infection whether it be syphilis, chancroid, granuloma inguinale or lymphogranuloma venereum.⁹⁴ Fusospirochetes are not necessarily destroyed by intravenous arsphenamine therapy, intramuscular bismuth therapy, or by antimony compounds. These secondary invaders are best treated by topical applications of arsphenamines or by oxidizing agents such as *sodium perborate* or *zinc peroxide*. A mixture found to be very useful in the treatment of fusospirochetosis contains 7 to 10 per cent of arsphenamine in equal parts of cod liver oil and glycerine. Some analgesic may be added to this mixture when its application proves painful.⁹⁵ At the U.S.P.H.S. Medical Center penicillin parenterally and locally has proved of worth in a small series of cases. Dusting with vioform powder has been helpful in controlling several recalcitrant lesions.

Malignancy—Malignancy must be differentiated from the ulcers of esthiomene, anorectal syndrome, genital syndrome and the inguinal syndrome. This is best done by histopathologic study of biopsy specimens.⁴³

Tuberculosis—Biopsy of the tissues will show typical tubercle formation, and the demonstration of tubercle bacilli in spreads and transmission of the disease to animals by inoculation establish the diagnosis of tuberculosis.

Filariasis and Schistosomiasis.—Members of our armed forces are being exposed to these conditions in the South Pacific, Egypt, Africa and the Orient. *Filaria bancrofti* causes elephantiasis of the lower extremities and scrotum, less frequently of the vulva. Demonstration of filaria in stained, thick blood films or in the lymph from the elephantiasis areas establishes the diagnosis of filariasis.⁹⁵ Elephantiasis, common among natives, does not seem likely to develop among our troops, judging from present trends.⁹⁶

Schistosomiasis.—Schistosomiasis may simulate the genital and anorectal syndromes of lymphogranuloma venereum. Actual elephantiasis of the penis with fistulous openings draining purulent material may result from this parasitic disease. The demonstration of the typical ova in the urine and feces serves to establish the diagnosis.⁹⁷

Tularemia, Hodgkin's Disease and Regional Adenitis—These may simulate the inguinal bubo of lymphogranuloma venereum. Tularemia may be differentiated by its specific agglutination reaction and demonstration of the specific organism in the suppuration.⁹⁸ Hodgkin's disease may be differentiated by the biopsy and histopathologic study, regional adenitis by demonstration of the causative organism or the presence of local infection.

Actinomycosis.—Actinomycosis may be differentiated by demonstration of the ray fungus in the discharges from the sinuses.

TREATMENT

Chemotherapy—Sulfonamides are the treatment of choice in lymphogranuloma venereum. The effectiveness of sulfonamide therapy is inversely proportional to the duration of the infection. Utilized in the early stages of any syndrome of lymphogranuloma venereum the progress of the condition is arrested, ulcerative processes heal, the buboes regress, proctitis ceases, the urethral discharge improves⁹⁹. Continued long enough, the sulfonamides produce clinical regression or arrest in 80 per cent of the inguinal cases and marked improvement in the anorectal cases¹⁷. Regardless of the stage of lymphogranuloma venereum, sulfonamide therapy is often effective in checking pain, discharge and progression⁹⁹.

Sulfathiazole and sulfadiazine seem to be the drugs of choice of most investigators,^{32, 99 100, 101 102} although sulfaguanidine and sulfasuxidine have been suggested for the rectal syndrome because of their poor absorption^{36, 103}. Sodium sulfanilyl sulfanilate has been utilized by another group of investigators for rectal syndrome with apparently excellent results^{104 104a}. A course of 4 gm of sulfathiazole daily for two weeks, alternating with rest periods of two to three weeks, continued through a minimum of a year has been found effective in anorectal disease with proctitis¹⁰². Recurrences have been brought under control with additional sulfathiazole. Lymphogranuloma venereum conjunctivitis has been cured by sulfadiazine¹⁰⁵. The average early case at the Medical Center is given 1 gm of sulfathiazole four times daily for a week or ten days, then, after a week's rest period, an identical, second course. If indicated by the clinical response, more courses may be given. The average total dosage varies between 56 to 80 or more grams. A white blood count and differential should be done weekly. Complications observed have been agranulocytopenia, mild fever and dermatitis medicamentosa, all of which cleared on withdrawal of the drug.

A note of caution must be added concerning the efficacy of the sulfonamides in rendering the lymphogranuloma venereum agent avirulent. Investigators have found that dosages of sulfonamides sufficient to protect inoculated mice against the agent apparently do not render the agent avirulent. Successful transmission of the disease to other mice has occurred following inoculation of brain substance from "protected" mice^{106 107 108}. Treatment apparently lowers the concentration of the agent but does not affect its virulence¹⁰⁸. The future epidemiology of lymphogranuloma venereum should reveal whether we are producing asymptomatic carriers by sulfonamide therapy.

The advent of *penicillin* in the therapy of syphilis has given an opportunity to watch its effect upon lymphogranuloma venereum in coexistent infections. In a series of cases observed at the United States Public Health Service Medical Center in Hot Springs, dosages of penicillin varying from 600,000 Oxford units to 2,400,000 units failed

to affect the ulcers or the buboes of lymphogranuloma venereum. One case actually developed inguinal buboes while receiving 2,400,000 units of penicillin (PLW). In all these cases the sulfonamides subsequently caused clinical response. Evidently, in the dosages used, penicillin has no effect upon lymphogranuloma venereum.

Aspiration—Fluctuant buboes should be aspirated—never incised. Where local complaints call for immediate relief or where perforation is imminent, the pus should be aspirated. This gives the same instantaneous effect, creates a better wound and furnishes sterile material for Frei antigen and the inverted Frei test.

Vaccinotherapy—Vaccinotherapy has been utilized by (a) subcutaneous,^{90 100 110} (b) intracutaneous^{88 99 111 112} and (c) intravenous routes,^{90 113 114 115 116} or (d) combined with sulfonamides^{117 118}. Ascending dosages of vaccine are injected at five-day to weekly intervals, beginning with 0.05 cc and increasing 0.01 cc, as indicated, to the maximal dosage of 1 cc. The combined form of therapy has been recommended in the more chronic forms of the disease.^{90 109} In the sulfasensitive individual vaccinotherapy may be the only available method of treatment.

Convalescent Serum—Five cubic centimeters of convalescent serum was injected intramuscularly at weekly intervals, by one group of workers with apparent good results.¹¹⁹

Surgery—The removal of the polypoid pedunculated tumors and elephantiasic vulvae is often advisable. Healing readily takes place, but recurrences several years later have been noted. Matted nodes that have remained indurated for months may require total extirpation.^{111 116 120} This procedure is attended by the danger of lymphatic obstruction and chronic elephantiasis of the pudenda, as an operative complication. As a general practice, excision should be deprecated and aspiration preferred. Ileostomy and colostomy may be necessary due to intestinal obstruction caused by rectal stricture.

Management of Rectal Stricture—(a) The *sulfonamides* reduce the pain, proctorrhoea and other secondary manifestations of rectal stricture. Continued over long periods of time, with intervening rest periods, a few cases have been reported to go on to clinical "cure". (b) When chemotherapy is combined with *vaccinotherapy*, excellent results have been reported.^{113 114} (c) In addition to chemotherapy the stricture should be gently *dilated* at weekly intervals. This may be accomplished by manual or mechanical dilatation (Hegar dilator). (d) *Physiotherapy* in the form of long or short wave diathermy has proved effective in softening the inflammatory process and relaxing the stricture. Constipation is often markedly improved after dilatation and physiotherapy. If dilatation is so painful as to preclude the cooperation of the patient, caudal block or general anesthesia may be utilized to dilate the stricture thoroughly. Gentle manipulation must be employed to prevent further damage and scarring. Unless manual

dilatation is performed at weekly intervals for several months, recurrence of the stricture takes place Sulfonamide therapy should be instituted immediately following surgical dilatation, satisfactory and permanent results have been observed¹¹² (e) When strictures are beyond the reach of the examining finger, colostomy may be a justifiable procedure It must be remembered that if fibrous tissue has completely replaced inflammatory tissue, clinical cure cannot be accomplished, only clinical improvement may be attained

CONCLUSIONS

1 Lymphogranuloma venereum in its early uncomplicated stages can be diagnosed and treated by the general practitioner in his office

2 It occurs with greatest frequency along seacoasts, is often associated with other venereal diseases and in the United States is relatively much more frequent in the Negro race

3 It is highly infectious and is communicable while an open lesion or draining sinus exists It is a systemic disease

4 Diagnosis is based upon the clinical picture, a positive Frei test and a positive complement fixation test (titer 1-80 or higher)

5 It must be differentiated from the other venereal diseases, tuberculosis, malignancy and some exotic conditions

6 The sulfonamides, preferably sulfathiazole and sulfadiazine, are the treatment of choice In chronic cases vaccinothrapy may be combined with sulfonamides

7 Penicillin in dosages from 600,000 to 2,400,000 Oxford units has not proved of worth in treatment of lymphogranuloma venereum

8 Surgery should be conservative, confined to removal of elephantiasic and polypoidal growths

PENICILLIN-RESISTANT GONORRHEA

CAPTAIN RICHARD L SAUNDERS AND CAPTAIN MURRAY M MAY
MEDICAL CORPS, ARMY OF THE UNITED STATES

In the spring of 1944, at Hammond General Hospital, 212 consecutive cases of sulfonamide-resistant gonorrhea in the male were treated with intramuscular injections of penicillin. Of this number, seventeen patients or 8 per cent were not benefited by the penicillin treatment. As other reports dealing with penicillin therapy in the treatment of uncomplicated gonorrhea in the male state that 98 to 100 per cent cures are obtained,^{1,2} the failure of penicillin therapy in 8 per cent of the patients in this series is unusual and requires careful analysis. No reports dealing specifically with failure of penicillin therapy in the management of gonorrheal infections have appeared in the literature to date.

TABLE 1—THE AMOUNT IN UNITS AND NUMBER OF COURSES OF PENICILLIN ADMINISTERED TO THE ENTIRE SERIES OF 212 PATIENTS, IN RELATION TO THE FAILURES OF THERAPY

No. Cases	1st Course	2nd Course	3rd Course	Total per Patient	No. Failures
106	50,000			50,000	0
15	50,000	100,000		150,000	0
9	50,000	100,000	200,000	350,000	5
1	50,000	200,000	800,000	1,050,000	1

17	100,000	100,000		200,000	0
1	100,000	100,000	100,000	300,000	1
1	100,000	100,000	300,000	500,000	1
212					17

The first course of treatment in the 212 cases was administered according to Army directive.³ In all of the seventeen cases listed as failures the patients received three courses of treatment with penicillin before failure of therapy was considered to be established (Table 1). Although the criteria of cure in the 92 per cent in whom penicillin was adjudged effective may be subject to some question, the evidence of failure in the 8 per cent is obvious.

ANALYSIS OF CASES IN WHICH A CURE WAS OBTAINED

All injections of penicillin in this series were given by the intramuscular route at three-hour intervals. An analysis of the 195 cases which

met the criteria of cure is given in detail in Table 2. One hundred and twenty-five patients were treated with an original course of 50,000 units in doses of 10,000 units every three hours. One hundred and six of these or 85 per cent were cured with a single course. A second course of 100,000 units added 12 per cent additional cures. A third course yielded 3 per cent additional cures.

Seventy patients were treated with an original course of 100,000 units given in doses of 20,000 units every three hours. Forty-seven of these or 67 per cent were cured with a single course. A second course of 100,000 units added 24 per cent additional cures. A third course resulted in 9 per cent additional cures.

Criteria of Cure—Using an Army directive dated September 23, 1943⁸ as a basis, the following regimen and criteria of cure were adopted. If there was no evidence of discharge for three days after

TABLE 2—THE AMOUNT IN UNITS AND NUMBER OF COURSES OF PENICILLIN USED IN 195 PATIENTS WHO WERE CONSIDERED CURED, AND THE PERCENTAGE OF CURES FROM ONE COURSE OF TREATMENT AND THE PERCENTAGE OF ADDITIONAL CURES FROM EACH SUBSEQUENT COURSE

No. Cases	1st Course	2nd Course	3rd Course	Total per Patient	Per Cent Cured
106	50,000			50,000	85
15	50,000	100,000		150,000	12
4	50,000	100,000	200,000	350,000	3
<u>125</u>					<u>100</u>

treatment, freedom from infection was assumed. If discharge persisted or recurred by the second day, smears and cultures of the discharge were made. If these were negative the patient was also assumed to be free of infection. In cases of persistent discharge and positive smears, further penicillin treatment was instituted. From the beginning of this study it was decided to insist on a negative culture either from urethral discharge, from urine, or from prostatic secretion before disposition of the patient was made. This culture was taken at least forty-eight hours after treatment was completed.

It is obvious that such a short follow-up of the effectiveness of therapy by penicillin injections is unsatisfactory statistically but it was not practical to retain a large number of patients in the hospital for follow-up observations as it may be assumed that the majority of cases would remain smear and culture negative. However, the work of Koch and his associates showing a relapse rate of 32 per cent in

three months,⁴ reveals the importance of follow-up cultures, and indicates that the percentage of failures in this series would be increased beyond 8 per cent if a prolonged follow-up of our patients had been possible

ANALYSIS OF FAILURES

An analysis of the seventeen patients in whom penicillin therapy was ineffective reveals that repeated courses of treatment with large doses of penicillin were of no avail in this group (Table 3). It should again be emphasized that each patient in this group of therapeutic failures was treated with three courses of penicillin. One patient received a total of 300,000 units, five patients received 350,000 units, nine patients received 400,000 units, and one patient received 500,000 units. One additional patient was given a total of 1,050,000 units, 800,000 units being given during the third course, without beneficial effect. It is noteworthy that the same three-hour interval between doses was used in all courses of treatment and that the maximum single dose given in

TABLE 3 —THE AMOUNT OF PENICILLIN IN UNITS EMPLOYED IN THE TREATMENT OF SEVENTEEN PATIENTS IN WHOM PENICILLIN THERAPY WAS INEFFECTIVE

No. Cases	1st Course	2nd Course	3rd Course	Total per Patient
5	50,000	100,000	200,000	350,000
1	50,000	200,000	800,000	1,050,000
9	100,000	100,000	200,000	400,000
1	100,000	100,000	100,000	300,000
1	100,000	100,000	300,000	500,000
<u>17</u>				

any case was 20,000 units. In those patients receiving more than 100,000 units during a course of treatment, the duration of the treatment period was extended beyond the usual fifteen hours until the total dosage was accomplished. For example, the one patient who received 800,000 units during the third course of treatment (Table 3), was given 20,000 units every three hours for 120 hours.

In this group of seventeen failures, there were seven patients whose cases were considered to be new, in that the history indicated that infection had been present less than six months. The other ten cases were designated as chronic in that symptoms had existed for more than six months.

Possible Causes of Failure —The reason for the failure of penicillin to eradicate infection with the gonococcus in this group of cases remains unexplained. The possibility that some technical difficulty was responsible was explored. However, it was obvious that cures were being effected at the same time that the failures in therapy were occurring.

Changing the brand of penicillin that was being used to another brand manufactured by a different pharmaceutical firm did not alter the percentage of failures. The potency of the penicillin against the Oxford strain of staphylococcus was tested. This strain was found sensitive in a dilution of 0.03 units per cubic centimeter, indicating that the penicillin was of satisfactory potency. Blood levels of penicillin were determined in two cases classified as failures (Table 4). This concentration was within a satisfactory therapeutic range. Tests also indicated that there was no difference in the potency of the penicillin in distilled water from that in saline.

That failure in therapy might be a biological one was also considered. The significant possibility that certain strains of gonococcus might be or become penicillin resistant was recognized, but sensitivity tests in vitro to determine whether penicillin resistance could account for our adverse findings could not be carried out in the hospital laboratory. Relative to this problem, a communication from Major Ayer, Chief of Laboratory Service of the O'Reilly General Hospital, Springfield, Missouri on March 28, 1944, stated that "Penicillin sensitivity tests during

TABLE 4—THE PENICILLIN BLOOD LEVELS IN TWO PATIENTS IN WHOM PENICILLIN FAILED TO CLEAR UP GONOCOCCUS INFECTION, THE TITER IS WELL WITHIN THE EFFECTIVE RANGE

CASE I	1.25 units/cc. one-half hour after second dose of 20,000 units
	0.078 units/cc. one and one-half hours after second dose of 20,000 units
CASE II	0.62 units/cc. one-half hour after second dose of 20,000 units
	0.078 units/cc. one and one-half hours after second dose of 20,000 units

the past four months have not disclosed any strain of *N. gonorrhoea* that was initially or has become resistant to the therapeutic agent. The organisms fell invariably within a range of 0.005 to 0.05 units per cc. for complete inhibition. This is true even for organisms isolated from patients who were not cured after receiving 100,000 units." Recent publications on the elaboration of antipenicillin substance by certain bacteria do not include the gonococcus except in one instance. This substance has been termed penicillinase by certain writers and one strain of gonococcus has been reported as negative for the production of penicillinase.⁵ To date, positive evidence is lacking that certain strains of the gonococcus are resistant to penicillin.

MANAGEMENT OF THE PENICILLIN RESISTANT CASES

The treatment of seventeen penicillin-fast patients proved an interesting though difficult problem. One patient who had received 400,000 units was subsequently cured with *sulfathiazole*. This patient was the only one in the series who had not previously received sulfonamide therapy. He was included in the series in order to emphasize the fact that in some instances sulfonamides may be effective even though

penicillin has previously failed. One patient was cured after a *meatotomy* was performed and urethral irrigations with potassium permanganate, 1 10,000 solution were administered. One patient had a marked diverticulum of the urethra. Surgery was not considered advisable and he was given a course of potassium permanganate irrigations which proved ineffective. This patient was discharged to a Veteran's Facility and it was not possible to follow his ultimate course. The remaining fourteen cases were referred to the genito-urinary section of the Surgical Service for *fever therapy*. The average duration of the therapeutic fever was fourteen hours during which time the fever was maintained between 104° and 106° F. The general plan of treatment for these patients was as follows:

If no urethral discharge was noted after the fever therapy, no further treatment was given. Five days after fever therapy or after cessation of the discharge, cultures from the prostatic secretion were made. After three consecutive negative cultures made at approximately forty-eight-hour intervals, the patient was pronounced cured. If urethral discharge persisted, the patient was given daily *irrigations of potassium permanganate solution* and *prostatic massage* twice daily. This treatment was continued until the discharge had ceased and three successive prostatic smears were negative. If there was no cessation of the discharge after irrigations, the urethra was examined for obstruction.

In four patients the urethral discharge ceased within a few days after fever therapy was started and irrigations were not given. In these cases, prostate cultures were taken within the first ten days following fever, and, after three negative cultures, the cases were pronounced as cured. All four of these patients were returned to duty. In this group the cure can be directly attributed to the fever therapy.

Following fever therapy, four patients continued to have urethral discharge which was negative for gonococci. Urethral irrigations and prostatic massage were continued until the cessation of the discharge. The average period of this treatment in these patients was one month. Subsequent prostatic cultures were negative. Three of these patients were returned to duty and one was given a medical discharge because of a psychiatric diagnosis. Fever therapy probably contributed to the eventual cure of this group of patients.

Four patients continued to have a urethral discharge which was positive for gonococci. This discharge continued for about a month after the last bout of fever. During this time urethral irrigations and prostatic massages were carried out. Upon cessation of the discharge, prostatic cultures were taken. When these were negative, the cases were pronounced cured. Two were returned to duty, and two were discharged from the Army because of psychiatric diagnoses. These four cases were classed as definite failures from fever therapy.

Two additional patients were not cured by either fever therapy or

irrigations. They continued to have a profuse urethral discharge which was positive for gonococci. Repeated prostatic and urine cultures were also positive. One of these patients had a severe urethral stricture and was finally discharged from the Army for this reason. The other patient was transferred to another hospital and follow-up inquiry disclosed that five months after fever therapy the urethral discharge ceased and prostatic cultures were negative without benefit of further treatment.

DISCUSSION

The problem of why 8 per cent of these cases of gonorrheal infection failed to respond to penicillin therapy remains unsolved. Also why treatment of 125 cases with a single total course of 50,000 units of penicillin produced cures in 85 per cent while a single course of 100,000 units in seventy cases produced cures in only 67 per cent is difficult to explain. It seems probable that different strains of the gonococcus may vary in their susceptibility to therapy and that cures will not be so readily obtained in any series of cases which may contain a large number of the more resistant strains. Clear-cut biological evidence of this explanation is lacking at present.

Three of the seventeen patients classified as failures on penicillin therapy were discharged from the hospital as not cured, although one of these patients was ultimately reported from another hospital as free of discharge and culture negative. The effect of fever therapy in fourteen patients in this group is difficult to evaluate because other therapeutic procedures were carried out in all but four cases and because there was no prolonged follow-up study of any of the cases to determine whether the patients remained "cured" symptomatically and bacteriologically. For the period of observation, the four patients who received fever only were apparently cured, while two patients were not cured as they remained smear and culture positive. Although eight other patients became bacteriologically negative these negative tests were obtained while the patients were receiving irrigations and can scarcely be accepted as final proof of cure. Nevertheless patients with gonorrhea which do not respond satisfactorily to therapy by sulfonamides and penicillin should have a trial of fever therapy.

One other factor seems to be of importance in treating these patients and that is adequate drainage of the urinary tract. Three of the "failure" patients had obstructive lesions. These were (1) a small meatus for which meatotomy was performed, (2) a marked diverticulum of the urethra and (3) a severe urethral stricture. That this type of case with mechanical obstruction of the urethra may not respond to penicillin therapy unless the obstruction is removed, is borne out by the history of a case recently observed and not included in the original series. This patient had been treated unsuccessfully with sulfadiazine and with penicillin. The dose of penicillin used was initially 20,000 units and then 10,000 units every three hours for eighteen doses.

for a total dosage of 200,000 units. Because the patient had a narrow urethral meatus and marked phimosis, a meatotomy and circumcision were performed. Penicillin therapy was started twelve hours pre-operatively in a dose of 20,000 units every three hours and was continued for seventy-five hours to complete a total dosage of 500,000 units. The discharge cleared up on the fourth day after treatment was started and on the seventh day smears and culture were negative.

SUMMARY AND CONCLUSION

1 In a series of 212 patients with sulfonamide-fast gonorrhea treated with penicillin, seventeen failures (8 per cent) occurred.

2 The possible cause of the high percentage of failures in this series is unknown.

3 The management of these patients with penicillin-fast gonorrhea is discussed.

4 A certain number of patients with gonorrhea may not be cured by either sulfonamides or penicillin therapy. Failure of cure by repeated courses of penicillin therapy in seventeen of 212 cases, or 8 per cent, is a higher incidence of failure than previously reported. Some of the patients who were not cured by chemotherapy were apparently cured subsequently by fever therapy and by operation to relieve urethral obstruction.

ACUTE ACQUIRED HEMOLYTIC ANEMIA

LT COLONEL GARNETT CHENEY AND MAJOR EDWARD J. DENENHOLZ
MEDICAL CORPS, ARMY OF THE UNITED STATES

It has been pointed out that acute hemolytic anemia may develop as a result of a variety of etiologic agents, such as hemolysins of the immune body type, agglutinins, chemicals, bacteria and other infectious agents.¹ This clinical picture may also occur as a manifestation of an underlying systemic disorder such as Hodgkin's disease or leukemia, and to this latter type the term "symptomatic hemolytic anemia" has been applied.² In the recent literature, considerable attention has been directed to acute hemolytic anemia following administration of sulfonamide drugs,³ following the development of anti-Rh agglutinins in the newborn,⁴ and in Rh-negative individuals during pregnancy or after repeated transfusions⁵ and occurring in association with cold hemagglutinins.⁶ In addition to these groups, however, there is a type of acute hemolytic anemia which develops in a previously healthy individual and for which no etiology can be determined. These cases have been termed "acquired hemolytic icterus," "acute hemolytic anemia," "acquired hemolytic anemia,"⁶ and the Hayem-Widal type of hemolytic anemia.⁷ In some of these patients antibodies of an immune body type⁸ may be detected, but in the majority no such serologic findings are present. A patient with acute acquired hemolytic anemia of unknown etiology observed at Hammond General Hospital, presented some of the characteristic features of this condition, but also demonstrated several rather unusual aspects of the disease, and its treatment.

REPORT OF THE CASE

History—This 24 year old white male with two and one half years of military service was admitted to Hammond General Hospital April 25 1944 by transfer from a station hospital. He stated that he had "never been ill" and had always been unusually healthy. It was later learned that he was the outstanding athlete at his post. About three months before entry to the hospital he noted that, following vigorous athletic activities, he became fatigued more readily than usual. Early in April following a basketball game, he developed nausea, headache, dizziness and weakness, lasting for several hours. The following day a medical officer who passed him in the corridor noted his pallor and suggested that a blood count be made. This revealed red blood cells 2 100 000; hemoglobin 45 per cent; leukocytes 11,650 with 62 per cent polymorphonuclears. The patient was admitted to the station hospital where during the course of the next ten days he received three blood transfusions of 500 cc. each. The red blood cell count following his third transfusion was 1 860 000 and hemoglobin 40 per cent, and for this reason he was transferred to a general hospital. There was no history of exposure to or ingestion of drugs. There was no history of a similar illness in any other member of the family.

Physical Examination—The patient appeared toxic and acutely ill and presented marked pallor with slight icteric tinge to the skin and mucous membranes. The temperature was 102° F, pulse 110 and respirations 28. The cheeks were flushed and the vessels in the neck were pulsating. There were no purpura or petechiae. There was a soft systolic murmur over the third interspace to the left of the sternum, which was interpreted as being hemic in origin. The liver and spleen were palpable at the costal margin. No adenopathy was present.

Laboratory Findings—Initial *blood studies* showed red blood cells 1,440,000, hemoglobin 27 per cent, leukocytes 24,550 with 65 per cent polymorphonuclears and 29 per cent lymphocytes. There were 26 nucleated red cells per 100 white cells and 54 per cent reticulocytes. The platelet count was 120,000. The stained smear showed a moderate number of small dense cells, large slate-gray cells and many small nucleated red cells with dense pyknotic nuclei. There was marked polychromatophilia and basophilic stippling. Hematocrit was 15 per cent, volume index 113 and average red cell diameter was 7.5 microns by the halometer method. The fragility test showed initial hemolysis beginning at 0.60 and complete at 0.44. The icteric index was 50. The serum proteins were 11.2 gm, albumin 5.5 gm and globulin 5.7 gm per 100 cc. The urine was negative for bile, positive for hemoglobin and positive for urobilinogen in a dilution of 1:50. The blood group was O, and the patient was Rh-positive. Neither hemolysins nor agglutinins could be demonstrated. Blood studies on the patient's two sisters including blood count, fragility test and icteric index yielded normal findings.

X-rays of the chest, skull and long bones were negative.

Management and Course—The patient was given 500 cc of citrated blood from a Group O donor after careful compatibility tests at ice box, room and incubator temperatures. Despite this, the following day the blood count was essentially unchanged, and he appeared worse. The urine was deep reddish-purple in color, showed only a few red cells and was markedly positive for hemoglobin. Inasmuch as the patient had had four blood transfusions with no apparent improvement, and hemolysis was continuing, it was felt that a splenectomy was urgently indicated. Under spinal anesthesia, splenectomy was performed twenty-four hours after the patient entered this hospital. The operation was well tolerated and for a few days the patient appeared to be progressing fairly well. However, on the fourth postoperative day, the temperature rose to 104° F and the red cell count dropped to 1,020,000 with 26 per cent hemoglobin. There were 16,500 leukocytes per cubic millimeter and 23 per cent reticulocytes. It was recognized at this time that in view of the continuing hemolysis following splenectomy, the prognosis was poor. However, it was felt that there was no recourse other than a continuation of blood transfusions when the blood counts reached extremely low levels. Intramuscular injections of crude liver extract were started, and a transfusion of 500 cc of citrated blood was given. Sodium bicarbonate, 12 gm by mouth daily, was also begun to prevent the formation of acid hematin in the kidneys.

On the seventh postoperative day the red cell count had dropped to 860,000 with 24 per cent hemoglobin. The leukocyte count was 9000 and there were 130 nucleated red cells per 100 white cells and 11 per cent reticulocytes. The patient failed to develop postoperative thrombocytosis, the highest platelet count, 125,000 per cubic millimeter, being present on this date. A transfusion of 500 cc of whole blood was followed by a chill, fever of 105° F and reappearance of gross hemoglobinuria. At this time penicillin therapy, 50,000 units intramuscularly every three hours, was instituted, and continued for nine days until a total dose of 2,500,000 units was attained. There was no demonstrable beneficial effect. Fever continued to range to a peak of between 103° and 104° F daily. Repeated blood counts indicated little change. The serum protein at this time was 14 gm.

per 100 cc., which was attributed to the tremendous red cell destruction and the failure of the liver to convert and excrete the bilirubin protein complex. Generalized hyperesthesia with marked muscle tenderness was an outstanding feature. Gastrointestinal complaints anorexia and abdominal pain were also prominent. On the tenth postoperative day the patient was given 500 cc. of whole blood which was again followed by a similar severe reaction.

On the twelfth hospital day after satisfactory cross matching the patient was given 1000 cc of washed resuspended Group O red cells with no reaction (obtained from the blood donor center San Francisco, Red Cross Chapter). However within forty-eight hours the red cell count and hemoglobin had dropped to the pretransfusion level. This procedure was repeated at intervals of every two or three days, as indicated by the red cell count and the clinical course, although when the fourth washed red cell transfusion was given on the nineteenth hospital day the patient developed a severe chill and a temperature rise to 104.8 F. The following day however the red blood count was the highest that it had been since his entry to the hospital red blood cells 2,840,000, hemoglobin 50 per cent, leukocytes 15,600 with 82 per cent polymorphonuclears. There were 122 nucleated red cells per 100 white cells and the reticulocytes had decreased to 4.1 per cent. The leukocytes showed evidences of toxic changes with only a few young forms being present. Bone marrow biopsy done this day showed no evidence of leukemia or Hodgkin's disease.

Subsequent to this the patient's course was rapidly downhill. He developed edema, pain and coldness of the right leg and foot, and it was thought that a venous thrombosis was present. The temperature continued ranging to peaks of 103 to 104 F almost daily accompanied by generalized abdominal pain, marked anorexia and vomiting. Subsequently he was given washed red cell transfusions at intervals of two to five days. Following each of these, he developed a chill and a rise in temperature to 104 or 105 F. However, the relationship of the temperature rise to the administration of the blood cells was difficult to evaluate inasmuch as the patient had exhibited a high fever almost daily.

Hemoglobinuria disappeared although albumin, hyaline and granular casts and red cells appeared in the urine. The urine was positive for urobilinogen in a dilution of 1:50. Repeated fragility tests showed hemolysis beginning at 0.66 to 0.64 and complete at 0.48 to 0.44. Repeated examinations failed to show the presence of iso- or autoagglutinins or hemolysins. The striking evidence of bone marrow activity continued in the blood smears, so that on the twenty-fifth postoperative day there were 169 nucleated red blood cells per 100 white cells. On the thirty-first hospital day the patient developed chest pain, raised scanty blood stained sputum and developed increasing weakness, and dyspnea. Dullness, crepitant rales and diminished breath sounds were found over both lower lobes. An x-ray of the chest showed clouding of both lower lung fields.

On the day before the patient's death the blood count was red blood cells 1,590,000 hemoglobin 39 per cent, leukocytes 39,630 72 per cent being polymorphonuclears with 2 per cent young forms and 26 per cent lymphocytes. There were 7 cells per 100 white cells and reticulocytes were 4.9 per cent. The icteric index was 22. He lapsed into a coma and died on the thirty-fifth hospital day.

Pathologic Examination (Major Russell Kerr)—Spleen (Surgical Specimen)—The spleen measured 15 by 10 by 7 cm. on section the pulp was deep purplish in color, the trabeculae were discernible though the malpighian bodies were not distinct. Histologic section revealed marked congestion of the sinusoids, and wide separation of the malpighian bodies. Large phagocytic cells containing blood pigment were noted in the pulp and nucleated red cells were present in the sinusoids.

Bone Marrow (Biopsy)—Histologic examination revealed marked cellularity

of the marrow with the predominant increase being in erythroblastic cells. Many of the cells were nucleated red cells and megalocytes. Moderate activity of the myeloid cells was present but there was no evidence of "maturation arrest."

Autopsy—The pertinent findings were a thrombus in the distal portion of the splenic artery, multiple pulmonary thrombi with infarction, bilateral hydrothorax and hyperplasia of the bone marrow. Microscopic examination showed extensive hemorrhage throughout the lungs with complete infarction throughout some areas and the presence of obliterating thrombi in many of the medium-sized pulmonary vessels. The liver showed marked distortion of the architecture, distention of the sinusoids, hemosiderosis and in many of the sections there was actual necrosis of the liver cells. Sections through the kidneys showed mild parenchymatous changes in the convoluted tubules. Bone marrow sections corroborated the findings obtained previously at biopsy.

COMMENT

This patient was of unusual interest for a number of reasons. The occurrence of acute hemolytic anemia in a previously healthy individual in the military service is indeed rare. This is the first case of this type that has been encountered in approximately 11,000 admissions to this hospital, though two patients with chronic hemolytic anemia of the familial type and one patient with symptomatic hemolytic anemia have been observed. This latter patient was found to have an undifferentiated malignant tumor as the underlying basis of the hemolytic anemia. The presence of marked hemoglobinuria in this condition is likewise worthy of mention. Mason did not observe hemoglobinuria in any of the patients in his series,⁶ nor did Damashek and Schwartz.¹⁰

The problem of diagnosis was also of considerable interest. The patient was transferred to this hospital with the diagnosis of congenital hemolytic anemia. It was felt, however, that the absence of any history of anemia or jaundice in earlier life, the absence of a familial history of the disease together with the normal blood findings in other members of the family and the clinical picture of the illness militated against this diagnosis. No etiologic factor for the hemolytic anemia could be determined and in view of this and because of the characteristic blood findings, a diagnosis of acquired hemolytic anemia of unknown etiology was ventured. Briefly it may be stated that little is known concerning the cause and method by which hemolysis occurs in the patients. A discussion of the theories of pathogenesis, and mechanism of hemolysis in this condition are beyond the scope of this clinical report. Comprehensive presentations of these aspects and reviews of recent experimental work in this and allied disorders have recently appeared in the literature.^{3, 6, 8, 9}

The number of nucleated red cells of the normoblastic type noted in the stained blood smears was striking throughout the period of observation. The number ranged, as demonstrated on daily blood counts, from 26 per 100 leukocytes on the day of entry to this hospital to 169 per 100 leukocytes on the twenty-fifth postoperative day. Following this, evidence of bone marrow activity decreased rather markedly so

that for a week before exodus there were only 7 to 15 nucleated cells per 100 white blood cells. There was no correlation between the number of nucleated red cells and the severity of the anemia, the administration of blood transfusions or the clinical condition of the patient, except during the last week of life as noted. Spherocytes, on the other hand, though present were not a prominent feature in this patient at any time.

The use of penicillin was of particular interest and was felt justifiable since this disease in many respects presents the characteristics of an acute infection and since following splenectomy it appeared almost certain that the patient would succumb. Penicillin had no beneficial effect.

The employment of washed resuspended red cells instead of whole blood would seem to offer several advantages. The red cells suspended in saline are Group O cells, and contain no agglutinin. The agglutinins a and b which are present in the serum of Group O individuals, and may be a cause of reactions, need not be considered since the cells are suspended in saline and free of these agglutinins. Hyperproteinemia, such as was present in this patient, may be increased materially by the use of whole blood but not by washed red cells. On the other hand it has been pointed out that stored cells may be more fragile and that serum may have some antihemolytic property. The appearance of severe reactions in this patient following transfusion of washed red cells is difficult to explain, particularly since the reactions occurred only after the fourth transfusion of washed cells. This suggests the development of some isoimmunization, either with agglutinins or hemolysins though none could be demonstrated. Rh agglutinins did not require consideration since the patient was Rh positive. The histologic findings of the bone marrow biopsy and of the spleen were typical of this condition, as were the autopsy findings, including thrombosis and infarction of the lung.

CLINICAL PICTURE

The symptoms are dependent upon rapid destruction of blood and resemble an acute febrile illness with toxemia, progressive anemia and jaundice. The onset is usually acute in the course of a few weeks, or may be fulminating, the symptoms developing in less than a week. Mason⁶ feels that a careful history often reveals that the symptoms begin insidiously a few weeks to a few months before the patient consults a physician. Common early symptoms are weakness, generalized aching, dizziness, faintness on exertion and gastrointestinal symptoms such as anorexia, abdominal pain and vomiting. These symptoms are soon followed by those of anemia, anoxemia and jaundice. Fever is almost invariably present, may range from 101° to 105° F and is often accompanied by chills. If hemolysis is marked, prostrating shock may occur and hemoglobin appears unchanged in

The urine and stools are both dark though anuria or oliguria may develop

Physical examination reveals an acutely ill, toxic patient with fever, moderate to marked pallor and mild icterus. The veins in the neck are often seen to throb, there is a hemic murmur over the precordium and tachycardia is marked. In about one third of the cases the liver is moderately enlarged, and in about one half the spleen is palpable, though the enlargement is not marked. Venous thromboses of the extremities and infarcts in the spleen, lungs and nervous system are not unusual. The duration varies considerably and often is dependent upon treatment, though spontaneous remissions occur. Some cases respond to one or more transfusions, some to splenectomy, and in others the hemolytic process continues despite therapy. Mason has directed attention to a subacute or chronic form which may develop following acute hemolytic anemia, even after splenectomy, and he feels that this form is more common than the acute type.

Blood—The anemia is profound, and may be normocytic or macrocytic. The red cell destruction may be so great that drops in the red cell count of as much as 1,000,000 cells may occur in twenty-four hours and the red cell count fall to less than 1,000,000 cells per cubic millimeter. The stained smear shows a striking variation between small dense cells and large slate-gray red cells. The small cells are spherocytes or microcytes, which Mason⁶ terms "microspherocytes." The large cells are reticulocytes, and for this reason have been termed "pseudomacrocytes" by Damashek and Schwartz.¹⁰ In spite of the severe anemia, there is evidence of intense activity of the bone marrow in both the red and white cell series. Reticulocytosis may rise to 50 to 80 per cent and polychromatophilia with many nucleated red cells may appear. These normoblastic cells may reach extraordinarily high numbers in the blood, as in this patient. Leukocytosis, with a shift to the left, is also a characteristic feature. The platelet count is usually normal.

Increased fragility of red cells in this disorder was first described by Chauffard in 1907.⁶ In the majority of cases, however, the fragility test is normal though decreased resistance to hypotonic saline may occur. Among twelve patients reported by Mason the fragility test was normal in eight, and showed increased fragility in four. Some patients may show a wide range in the span of the fragility test.

Demonstrable hemolysins and agglutinins occur only infrequently in this disorder, though autoagglutinins and hemolysins were reported as early as 1908 by French clinicians. Mason was unable to observe hemolysins in any of his twelve patients though autoagglutinins were found in four patients. The significance of these antibodies and their importance in the pathogenesis of the disease is still a moot question, some recent articles emphasizing that these antibodies may result from

* excessive blood destruction rather than act as a causative agent.¹¹

It must be pointed out that the failure to demonstrate these antibodies *in vitro* does not preclude their presence.

As a result of the inability of the liver to handle the increased amount of bilirubin which occurs as a result of the red cell destruction, the bilirubin level of the blood is elevated, the blood serum reveals a high icteric index and the van der Bergh reaction yields a positive indirect result. Serum protein values may be elevated, as in this patient.

Urine—These findings are also dependent on the degree of the hemolysis. Bile is not present in the urine but urobilinogen is markedly increased. When the hemolysis is extreme, hemoglobin appears in the urine unchanged. Hemoglobinuria in this disorder is rare in adults,^{6 10} although is more frequent in children as noted by Atkinson.¹² Mason⁶ feels that this may indicate that in this disease the red cells are destroyed in the spleen after being injured in the blood stream, and only when the liver and spleen are overwhelmed does free hemoglobin enter the blood stream. The urine may also contain albumin, granular and cellular casts. Bilirubinuria develops only in the presence of severe liver damage.

Stools—Urobilinogen in the stools is greatly increased and the diagnostic importance of this has recently been emphasized. Some observers consider that this is a far better diagnostic test than the presence of increased urobilinogen in the urine, and that it is the most important and most direct evidence of increased hemolysis.¹³

Bone Marrow.—Biopsy or bone marrow punch reveals marked evidence of hyperplasia, particularly of the erythroblastic cells. Instead of the normal 20 per cent or less, as many as 60 per cent of the cells may be of the normoblastic series. The similarity to megaloblastic marrow of pernicious anemia is superficial and in acquired hemolytic anemia there is no "arrest level" at the megaloblastic stage.

Pathology—In addition to bone marrow hyperplasia, there is usually moderate enlargement of the spleen with congestion of splenic pulp by red cells, multiple areas of thrombosis and infarction, and erythrophagocytosis by giant cells. Enlargement and hemosiderosis of the liver is often present. Necrosis of liver cells such as was present in this patient has been noted.^{6 14}

DIAGNOSIS

The diagnosis of this disease is usually made by exclusion. The sudden onset of profound anemia, icterus, toxemia and fever, particularly with splenomegaly, in a previously healthy adult is highly suggestive of an acute hemolytic process. In congenital hemolytic anemia there is often the history of the disease having been present since childhood, and the presence of a similar illness in other members of the family may be elicited. In this connection, blood studies on other apparently well

members of the family, such as were performed in this case study, are very valuable as a diagnostic aid. That the patient with the congenital form usually does not appear particularly ill has long been known and has recently been emphasized by Kracke⁷ who states, "the patient with the congenital type is more icteric than sick and the patient with the acquired type is more sick than icteric."

Spherocytosis and an increased fragility test are almost invariably present in the congenital type, but either or both may be absent in the *acquired* type. Bone changes may also occur in the congenital type, but have not been reported in the acquired form. The presence of biliary calculi has been cited as indicative of the congenital form though Mason has noted this complication in the chronic form of acquired hemolytic anemia. All other causes of hemolytic anemia must be excluded. In a patient who has atypical pneumonia, or who is taking sulfonamides, or who has leukemia or Hodgkin's disease, the etiologic factor may be readily evident. However, in the absence of these more common conditions, the less frequent causes of acute hemolysis such as exposure to industrial poisons, ingestion of fava beans or the presence of a tropical fever must also be considered. When these disorders are excluded as possibilities, the diagnosis of acquired hemolytic anemia of unknown etiology is acceptable.

Leukemia may be simulated because of the extreme myeloid hyperplasia with the presence of myelocytes and even myeloblasts in the blood. Large numbers of myeloblasts, characteristic of acute leukemia are, however, not found in acquired hemolytic anemia. The acute blood destruction present in this disease, however, does not occur in leukemia. In the patients with the fulminating type with hemoglobinuria, other causes of hemoglobinuria must be considered. It should be kept in mind that hemoglobinuria is merely a symptom which indicates severe intravascular hemolysis. Kracke and Hoffman¹⁵ have recently emphasized the diagnostic significance of hemoglobinuria.

PROGNOSIS

The disease may be self-limited and either death or recovery occur in from two to six weeks. Recovery may be spontaneous in some cases, whereas in others dramatic improvement may follow even a single transfusion, so that some authors consider that normal blood may possess an antihemolytic property. To this particular group of cases the term "Lederer's anemia" has often been applied. Most observers however, now agree that there is no justification for such a designation, inasmuch as this type of the disease represents merely one form of acquired hemolytic anemia.^{6, 10} In other types not responding to blood transfusions striking results have followed splenectomy. In addition there is a group in which neither transfusion nor splenectomy is of any value in terminating hemolysis. It is of interest that in Damashek's

series of eighteen patients with acquired hemolytic anemia in whom splenectomy was performed, ten made a full recovery and eight died after splenectomy, four of these with continuing hemolysis¹⁶ In Mason's series of twelve patients five died, in three of these cases splenectomy had been performed This is in contrast to the congenital type in which the patient usually makes an excellent recovery after splenectomy When evaluating the results in the acquired type, it should be kept in mind that in patients who demonstrate continuing hemolysis after several transfusions and in whom splenectomy is not performed the mortality is almost 100 per cent. At present there is no definite method of value in predicting the outlook in a given case Damashek feels that the presence of an unusual number of nucleated red cells, such as occurred in this patient, and of marked myeloid hyperplasia with or without bilirubinuria is a bad prognostic sign Davis points out that in eighteen cases with increased red cell fragility in which splenectomy was performed, improvement occurred in twelve cases, while in twelve cases with normal fragility only one improved.⁹

In some patients who recover after splenectomy, the response to operation may be immediate The jaundice subsides, the anemia rapidly improves, and agglutinins or hemolysins usually disappear The reticulocytes may remain high from two to three weeks after operation. The leukocyte and platelet counts may sometimes rise to unusually high levels

In none of the recovered patients in Damashek's series did hemolysis recur Mason,⁹ however has emphasized that though splenectomy in the acute stage may be life saving, some of these patients may subsequently manifest a chronic course interrupted by hemolytic crises of variable intensity In his series of twelve patients, five were of this type. He points out that in the chronic stage the disease may be complicated by obstructive jaundice fibrosis of the liver, and biliary calculi.

TREATMENT

When this disease is recognized, treatment should be prompt. *Blood transfusions* should be used not only to replace the diminished red cells and hemoglobin but also because they may have a dramatically curative effect There are, however, some precautions which should be observed in administering blood transfusions in these patients First, because of the presence of possible hemolysins and agglutinins in the patient's serum, donors of the same group as the patient should be employed wherever possible It should be remembered that the serum of the universal donor, Group O (Type 4 Moss) contains agglutinins a and b Intragroup agglutination should be watched for, particularly in Group A patients and those who are Rh negative and who have had several transfusions. Damashek and Levine¹⁷ have recently reported the

development of anti-Rh agglutinins in an Rh-negative patient with acute hemolytic anemia, who received a number of transfusions. The blood typing should be done by the Landsteiner-Levine technic and tests for auto- and isohemolysins should be performed. Icebox (4°C), room (20°C) and incubator (37°C), temperatures for the cross-matching should be used. The use of washed resuspended Group O red cells may offer considerable advantage in those patients in whom repeated transfusions are needed, in those who manifest hyperproteinemia, in those who develop reactions following whole blood transfusions and in those who demonstrate intragroup agglutinins, such as Rh-negative individuals.

The administration of *alkali* is of value in preventing the formation of acid hematin in the kidney tubules. If the patient tolerates it, large doses of sodium bicarbonate, 10 to 20 gm in twenty-four hours, may be given by mouth, otherwise 200 to 400 cc of a 2 to 3 per cent solution can be given intravenously. Iron therapy is not necessary, since the iron from the destroyed red cells is available for utilization. *Liver extract* may be used in patients who show evidence of bone marrow exhaustion or continuing hemolysis, though most of the patients with this disorder show intense bone marrow activity.

If improvement follows one to three transfusions given at intervals of twenty-four to seventy-two hours, no other therapy is indicated. When the patient continues to have hemolysis, however, after several transfusions, it is the consensus that *splenectomy* should be performed and that one should not wait too long before resorting to this procedure.¹⁶ There is a tendency among some clinicians to feel that the patient will not be able to withstand the operation, but it should be recognized that without splenectomy the outcome is often hopeless. There is no doubt that in a number of cases splenectomy has been life-saving. Spinal anesthesia is probably preferable. The operation should be done as rapidly as possible by a skilled surgeon, and the possibility of an accessory spleen considered at the time of the laparotomy. Blood transfusion may often best be delayed particularly in a patient who has had reaction to previous transfusions until the spleen has been removed, or until the splenic artery has been ligated. Some observers prefer the injection of 1 cc of adrenalin into the spleen preparatory to removal, though others feel that this may discharge the hemolysin that may be in the spleen into the circulation. The administration of heparin and dicoumarin have been suggested following splenectomy to avert the thromboses that are often found at autopsy, presumably due to postsplenectomy thrombocytosis. The advisability of this procedure would seem to be as yet open to question, unless there is clinical suspicion of thrombosis. In the patient in whom severe hemolysis continues after splenectomy, therapy is usually hopeless and one has no recourse other than to resort to transfusions as was done in the case herein reported.

THE FUNDAMENTAL IMPORTANCE OF DIET IN THE TREATMENT OF PEPTIC ULCER IN AN ARMY GENERAL HOSPITAL

With Special Reference to Vitamin "U" Therapy

MAJOR VIRGIL J GIANELLI AND CAPTAIN VINCENT BELLAFFIORE
MEDICAL CORPS, ARMY OF THE UNITED STATES

FROM October 1942 to January 1943, patients with peptic ulcer on the Medical Service at Hammond General Hospital received two types of management. These different regimens were not planned previously but occurred as a result of the patients being observed on two separate sections of the hospital. The enlisted patients, who were cared for on the Gastrointestinal Section, received no routine medication, the treatment consisting mainly of the use of the army convalescent ulcer diet¹. The officer patients, who were cared for on the Officer Section, on the other hand, received a Sippy type of dietary regimen with routine medication consisting of alkalis, antispasmodics and sedatives. The clinical impression was obtained that the patients in the two groups appeared to fare equally well.

As a result of these observations, a type of regimen for ulcer patients emphasizing the dietary management was instituted. This regimen has been employed at this hospital since January 1943 and the observations made comprise the basis of this report. A small group of patients who did not respond to treatment with the ordinary convalescent ulcer diet were treated by the use of a diet rich in vitamin "U". The use of vitamin "U" diet and the response obtained in some patients in this group of recalcitrant ulcer cases observed at this hospital has been reported². The importance of diet in the management of patients with ulcer in the military service has also been noted by others³.

SOURCE OF CASES STUDIED

From January 1, 1943 to August 1, 1944, 11,411 enlisted personnel were admitted as patients to Hammond General Hospital. Of this number, 793 or 6.9 per cent were admitted to the Gastrointestinal Section of the Medical Service. This group of cases did not include patients whose condition was diagnosed as "neurasthenia gastrica" at the time of admission, as these patients were cared for on the Neuropsychiatric Service. Four hundred and seventy-eight or 60.3 per cent of the patients admitted to the Gastrointestinal Section were diagnosed as having peptic ulcer. In 442 or 92.5 per cent of these patients the ulcer was duodenal and in thirty-six or 7.5 per cent the lesion was gastric.

These patients were received from three main sources. The first and largest group was returned from overseas and these patients invariably had undergone weeks to months of treatment before departure from overseas but a few had developed recurrence during transportation by ship. The second group of patients was received from nearby station hospitals because they were not completely relieved by the type of management which had been carried out and because they were considered to require prolonged hospitalization. Nearly all of these patients presented definite symptoms of ulcer and many showed ulcer craters by x-ray. A third group of five patients was received from the Post Detachment and all of these presented active peptic lesions.

METHOD OF INVESTIGATION

A special effort was made to secure an accurate history of each patient's symptoms and treatment both in civilian life and in military service. Emphasis was placed on obtaining a detailed account of the diet at the time the patient developed symptoms in Army service. All previous military hospital data referable to the patient's illness was recorded chronologically on the clinical record.

On physical examination particular attention was paid to the patient's body habitus, state of nutrition, and the presence of localized epigastric tenderness. Early in the course of this study it was noted that the patients did not conform to any particular body type and that the distribution of body configurations was about the same as in any average group of young male adults. This observation was true during the entire eighteen months of the study. If the majority of patients with peptic ulcer in civilian life are tall, slender, nervous and apprehensive and tend to be psychoneurotic, it is possible that they seek medical aid and that a diagnosis of ulcer is made, so that they do not meet the requirements for entry into the military service. Inasmuch as approximately 90 per cent of the patients with peptic ulcer admitted to this hospital had symptoms indicative of the presence of that disease prior to induction, it is evident that their complaints were not dominant factors in their lives, that they were more stoic about them and that they did not visit doctors frequently. Many of this group had never consulted a physician concerning their recurrent indigestion and almost none of them had ever undergone a complete gastrointestinal investigation in civilian life. They were rarely given the proper diagnosis and readily passed Army induction examinations.

The usual routine laboratory procedures were carried out in all cases, including urine examination, blood count, blood Kahn test, stool analysis for blood, ova and parasites and gastric analysis by the alcohol test meal method. Gastrointestinal x-ray study was made even though recent gastrointestinal x-ray reports from other hospitals were available. In patients with gastric ulcer and in the majority of patients with gastric symptoms in whom the diagnosis was in doubt, gastroscopy

was also performed. All the patients suspected of having peptic ulcer received a thorough diagnostic investigation before a decision was made on the exact mode of therapy.

All patients on the section were seen by a consultant neuropsychiatrist if their symptomatology suggested that such a consultation was indicated. These patients were given clearance by the consultant in nearly all instances. It is of interest in this connection to note that during a three-months' period sixty-nine patients with persistent abdominal complaints were transferred from the Neuropsychiatric Service to the Gastrointestinal Section and in only one instance was a peptic ulcer found.

ROUTINE MANAGEMENT

Rest and Exercise—Except for a few patients with severe pain or with evidence of complications, all were allowed to be ambulatory and to leave the wards from time to time. One patient developed a perforation while remaining in bed, two patients were maintained at bed rest because of active bleeding, and one patient was restricted to bed rest because of partial pyloric obstruction. Ambulatory patients regularly indulged in the mild physical exercise regimen of Class IV as conducted by the Reconditioning Division and patients who in later convalescence were symptom-free carried out the more vigorous Class III calisthenics and sports, including volley ball. At one time eight symptom-free patients were transferred to the advanced Reconditioning Center and took part in a program requiring vigorous physical exercise including drills, hikes and various active sports. Provision was made for these patients to receive the convalescent ulcer diet and to obtain milk regularly between meals. All of these patients developed recurrence of symptoms and five showed fresh ulcer craters by x-ray.

Diet—Except for a few who manifested severe pain, or who presented signs of complications as noted, all patients started therapy on a convalescent ulcer diet. This diet was given according to War Department Technical Manual 8-500, a manual of hospital diets published August 13, 1941.¹ This diet consists of beverages made with milk, toast, white or graham bread, butter, moderate amount, cereals, refined, cooked or uncooked, cheese, cottage, cream and bland, desserts, bland, such as custards and puddings, eggs, any style, except fried, meat, scraped beef and bacon, fruit, cooked and strained, soup, creamed and puréed only, vegetables, strained and puréed only. No nuts, salads, sweets or condiments are permitted. Certain additions and modifications to this standard hospital diet were utilized and are considered valuable adjuncts. First, meat such as tender lamb or beef, usually ground, and fish or fowl were served once or twice daily from the beginning. Second, orange and tomato juices were served to all patients who accepted them readily. A few patients did not like these juices but very rarely did any patient maintain that these gave him

indigestion Raw bananas were served when available Soft vegetables such as summer squash, stewed tomatoes, carrots, beets, spinach, green peas, tender string beans, and asparagus tips were served without straining or puréeing Seedless jams and nutless candy were permitted The special convalescent ulcer diet rich in vitamin 'U' includes certain other food additions and is described below

Medications—No medications were given routinely Patients were permitted to take a Sippy powder or bicarbonate of soda symptomatically early in the course of their illness for symptomatic relief Antispasmodics were not used and sedatives were never given regularly Occasionally mild sedation was utilized for pronounced insomnia No attempt was made at alkalization as part of the treatment, and consistent sedation was not utilized in any case The majority of patients in this series received no medication for ulcer at any time during their hospital stay Certain medications were utilized in conjunction with the special vitamin 'U' convalescent ulcer diet These are discussed below

Gastric Lavage—This procedure was carried out only as a therapeutic measure in one patient who had pyloric obstruction, and who thus obtained symptomatic relief

Alcohol—Though the use of alcoholic beverages was forbidden, many patients left the hospital on authorized pass from time to time and a number of these obviously drank spirituous liquors In some of them an exacerbation of symptoms which could be attributed to the use of alcohol developed, but these symptoms usually subsided without special therapy

Tobacco—Patients were not limited in the use of tobacco and many smoked twenty or more cigarettes daily No untoward symptoms could be attributed to the use of tobacco in the form of cigarettes and in no case did the ultimate course of the illness seem to be affected in an untoward manner

Psychotherapy—Individual psychotherapy by a trained psychiatrist was not utilized in any of these patients The few who might possibly have benefited from this form of therapy were ultimately separated from the military service, by disability discharge

SPECIAL CONVALESCENT ULCER DIET WITH VITAMIN U

The use of a more liberal high caloric diet in the treatment of patients with peptic ulcer is not new The Meulengracht diet of 'treatment by food' is an established and widely used therapeutic procedure The special diet used at Hammond General Hospital is not only high in calories but also contains certain uncooked foods in addition to milk, such as raw eggs, large amounts of butter, fresh greens and olive oil, considered to be rich in anti-ulcer factor This anti-ulcer factor designated as vitamin "U" has been shown to be effective experimentally but has not thus far been proved to have a

therapeutic effect in the management of patients⁴ However, the results of therapy in thirty-one cases on this dietary regimen which includes vitamin "U" have recently been reported by Cheney² All the patients reported by him had failed to respond to conventional forms of therapy Improvement was found to be highly satisfactory in twenty-seven or 81 per cent of these cases

Of the 478 patients treated in the present group at this hospital, forty failed to show satisfactory response to the regular convalescent ulcer diet. The failures were placed on the special dietary regimen Each of these forty patients complained of persistent abdominal pain With one exception, all showed positive x-ray evidence of active ulceration despite long periods of previous therapy Many who were undernourished had failed to gain weight satisfactorily These patients received the following food additions to the regular convalescent ulcer diet

Breakfast Eggs 2, cooked 2½ minutes Butter, 2 pats (20 gm)

10 A M Eggnog, ⅓ liter

Dinner Butter, 1 pat (10 gm)

Salad, 1 serving with special olive oil dressing

3 P M Peanut butter sandwich (with or without jelly)

30 gm peanut butter (smooth)

1 pat butter (10 gm) Eggnog, ⅓ liter

Supper Butter, 1 pat (10 gm)

8 P M Eggnog, ⅓ liter

The eggnog formula 4 eggs (200 cc), sugar, 30 gm, vanilla, 2 cc, 20 per cent cream, 200 cc, milk, 550 cc

Salad may contain any or all the following lettuce, broccoli, watercress, romaine, parsley, tomato, avocado (all fresh)

Salad dressing recipe lemon juice, 160 cc, olive oil, 320 cc, salt, 10 gm, sugar, 30 gm.

This diet consists of approximately 4200 calories and contains approximately 150 gm of protein, 450 gm of carbohydrates and 250 gm of fat

Certain medications known to contain vitamin "U" were included in the treatment First, cerophyl tablets which are made from green grass stalks were given in a dose of 5 tablets (2.5 gm) three times a day after meals and five tablets at bedtime Second, hog stomach extract in the form of ventriculin was given in a dose of 15 gm three times a day Also, bile salts (Bilron) were regularly administered in half gram doses three times a day after meals, as they had been shown to be effective in enhancing the activity of vitamin "U" presumably by promoting the absorption of this fat soluble substance No other form of routine therapy was utilized

These patients remained on this dietary and medicinal regimen for

an average period of one month. Those in whom rapid relief was obtained were treated for a shorter period, whereas those in whom symptoms tended to persist or in whom weight gain was not satisfactory were treated for a longer period of time. Three patients had to be eliminated from this series because of lack of cooperation or for administrative reasons. All of thirty-seven who were able to follow the treatment in detail showed some improvement and thirty-four patients obtained complete relief. X-ray studies made after treatment showed negative findings or revealed only a persistent deformity of the duodenal cap indicative of quiescent ulcer. Approximately 80 per cent of the patients who were underweight gained 5 pounds or more during treatment. The three patients who did not improve as satisfactorily as the others continued to complain of some distress despite a lack of x-ray changes indicative of active ulceration. Two patients who were considerably underweight failed to gain weight although they became symptom-free rapidly and x-ray evidence of ulceration disappeared.

ILLUSTRATIVE CASES

The following three case reports illustrate the benefit of dietary therapy in the management of patients with peptic ulcer.

CASE I—Duodenal Ulcer of Recent Origin Healed on Dietary Therapy Alone

—The patient was a 32 year old sergeant with one year and eight months of service, the last thirteen months of which were spent overseas. He stated that he first developed indigestion in March 1944 while on field rations. This consisted of upper abdominal, postprandial pain relieved by milk and alkalis. The pain usually recurred about one hour after eating and was particularly bothersome at night, often awakening him three to four times. He was returned to the main land and entered this hospital on June 21, 1944, three months after the onset of symptoms. He had followed a prescribed diet and taken medication continuously during this time, but his condition had not improved materially.

Moderate epigastric tenderness was present on physical examination. A gastrointestinal x-ray series showed a constant deformity of the duodenal cap with an ulcer crater. Gastric analysis revealed highest total acidity of 62 degrees and highest free hydrochloric acid of 50 degrees.

On June 22, 1944, this patient was placed on a convalescent ulcer diet. On June 26 he was still having considerable discomfort so that he was placed on more frequent feedings, receiving milk and cream, one glass every hour from 7 A.M. to 10 P.M. If he awoke during the night he was given more milk and cream. Divided portions of bland foods such as rice, potatoes and toast, and additional orange juice, were also added to the diet. By July 10 the patient was symptom free and was returned to the original convalescent ulcer diet. He continued symptom free. The gastrointestinal series was repeated on August 15 and showed a residual deformity of the duodenal cap but there was no tenderness, irritability or spasm and no ulcer crater was demonstrable.

Comment—This patient experienced persistent ulcer pain for three months despite dietary and medicinal therapy, but finally obtained complete relief from an adequate dietary regimen without any medications.

CASE II—Symptoms of Duodenal Ulcer Responding Only to the Special Dietary Regimen—The patient was a 31 year old technician, fifth grade, colored, with two years and four months of service, thirteen months of which were spent overseas. Upon entry to this hospital April 4, 1944, he stated that he had intermittent, recurrent epigastric pain since July 1943, which was relieved in the past on a Sippy regimen. He states that prior to July 1943 he had no similar complaints. A review of the transfer chart revealed that he had been treated with some type of ulcer regimen since July 15, 1943, at which time an x-ray series revealed a duodenal ulcer crater and a diagnosis of duodenal ulcer was made. He had received several trials of medications before entry to this hospital, including milk with calcium carbonate, gelatin solution, Sippy powder No. 2, tincture of belladonna and sodium amytal.

When this patient entered this hospital, he was having epigastric pain before meals, relieved by food, and was also complaining of considerable night pain. He weighed 133 pounds, which was 22 pounds below his normal weight. Gastric analysis revealed hyperchlorhydria with a total acidity of 75 degrees and a free hydrochloric acid of 57 degrees. An x-ray series showed a deformed duodenal cap with an ulcer crater. He was placed on a regular convalescent ulcer diet, but improved very slowly. On May 3 he was transferred to the Advanced Reconditioning Center. The convalescent ulcer diet was continued but the symptoms persisted and he failed to gain weight. On May 22 he was returned to the hospital for a repeat of the gastrointestinal x-ray series which revealed that the duodenal ulcer crater was still present. On May 23 he was placed on the special convalescent ulcer dietary regimen and by May 30 he was symptom-free for the first time. By June 28 his weight was 154 pounds, so that in thirty-six days on the special convalescent ulcer diet he had gained 21 pounds. On June 26 a gastrointestinal x-ray series showed no evidence of ulcer crater and no irritability of the duodenal cap.

Comment—This patient failed to respond to the conventional forms of dietary and medicinal therapy, but improved rapidly on the special dietary regimen containing Vitamin "U."

CASE III—Chronic Peptic Ulcer Relieved by Diet—This 34 year old staff sergeant with one year and nine months of service, none of which had been overseas, entered this hospital May 1, 1944. He gave a history of having first developed "indigestion" five years previously, and although x-ray investigation had never been undertaken he had been placed on a modified Sippy diet. He stated that in civilian life it had been his practice to follow this diet for periods of several weeks to several months after which he would abandon the treatment. After a few months the symptoms would recur, so that he would then again return to the Sippy diet to obtain relief. At the time of induction into the Army he was symptom-free and remained so until January 1944 when he was admitted to the hospital for two weeks because of duodenal ulcer. He returned to duty but on April 7 because of recurrence of symptoms he was again admitted to the Station Hospital and was then transferred to Hammond General Hospital.

Gastric analysis revealed hyperchlorhydria with total acidity of 90 degrees and free hydrochloric acid of 68 degrees. An x-ray series showed a deformed, irritable, tender, duodenal cap but no evidence of ulcer crater. He was placed on a convalescent ulcer diet and on June 12, after clinical improvement, he was transferred to the Advanced Reconditioning Center. At this time he was asymptomatic but the diet was continued. On June 30 he was readmitted to the hospital because of a return of his indigestion and on July 7 x-ray revealed a duodenal ulcer crater, with marked deformity, tenderness and irritability of the

duodenal cap On July 11 the special convalescent ulcer diet and medications were started His weight at this time was 145 pounds which was 10 pounds under his normal weight In three days he was symptom free but he had brief recurrences of pain on two occasions during the month of July Once, this recurrence of pain followed his participation in organized exercises. On August 8 a gastrointestinal x ray series was repeated and although a deformed cap was found, there was no tenderness, irritability or evidence of ulcer crater His weight was 149 pounds.

Comment—This patient is illustrative of the type of individual who has had a history of peptic ulcer for a number of years before entering the Army and who in civilian life was able to find an environment compatible with his disability He had recurrences of ulcer symptoms in the Army He responded to the regular convalescent ulcer diet until he was exercised regularly when an ulcer crater developed. He then showed rapid improvement on the special dietary regimen, with x-ray evidence that the ulcer had healed.

SUMMARY AND CONCLUSIONS

1 A total of 438 patients with peptic ulcer were clinically cured while taking a liberal convalescent ulcer diet. These patients received no routine medications of any kind Almost all of them were ambulatory throughout the course of therapy and all were permitted the use of tobacco

2 Thirty-seven additional patients who were not relieved while taking the convalescent ulcer diet were placed on a special high caloric convalescent ulcer diet containing raw foods and medications known to be rich in an anti-ulcer factor, vitamin "U", which has been shown to be effective in the treatment of experimental peptic ulcer Thirty-four of these patients (92 per cent) were completely relieved on this regimen

3 Although the use of dietary treatment alone has proved highly satisfactory in the management of patients with peptic ulcer in this series, it is recognized that this method of therapy may not be applicable to all patients with peptic ulcer and that other forms of treatment may be indicated in selected cases.

SYMPOSIUM ON REHABILITATION

INTRODUCTION

In a democracy every soldier has the right to expect the best equipment, the best food and clothing, and the best medical care. These things the American soldier has received and his record in combat attests how well he has used them. The scope of medical care in World War II has increased tremendously. It has been broadened to encompass not only definitive medical and surgical care, but new fields in preventive medicine and sanitation have also been explored and conquered. New concepts in the management of convalescence and rehabilitation have been created. The battle against disease and injury is not won when the last drop of sera has been given or the last suture placed in the incision. It is not won until the wounded veteran has been motivated, retrained, and reoriented for a useful, productive place in the community, either military or civilian. It is to fulfill this obligation that the armed forces have established comprehensive programs of rehabilitation and that certain vocational and educational opportunities have been made available to the veteran by congressional action.

But what has the disabled citizen in a democracy the right to expect? In the great manpower shortage which accompanies total war, the disabled citizen has proved his ability to produce as well as the normal man if he is placed in the proper niche. Industry has employed thousands of handicapped workers and has found that they have no handicap, if they are properly placed. Their production record, accident rate, and absentee record have equalled, or even excelled, the records of their normal co-workers. These people have *earned* the right to work, they have proved that they can do the job. It is up to the democracy to see that they are given the opportunity.

Rehabilitation is primarily a medical problem, but the doctor alone cannot *begin* to accomplish this mission. It is a job for team work, the doctor as captain of the team of specialists in the whole broad field of rehabilitation—physical educators, physical therapists, psychologists, occupational therapists, social workers, vocational guidance experts—all working together to treat the **WHOLE** man. We as physicians must rededicate ourselves to the treatment of the patient, not alone the disease. We must know the science of medicine but practice the art. We have new responsibilities and new opportunities in this great field of rehabilitation. It is our job to do.

HOWARD A. RUSK

Office of The Air Surgeon

CONVALESCENT CARE AND REHABILITATION IN THE ARMY AIR FORCES

A New Challenge of Postwar Medicine

COLONEL HOWARD A. RUSK*

MEDICAL CORPS, ARMY OF THE UNITED STATES

THAT all wars make some constructive contribution has once again been demonstrated by the technological and scientific advances, necessary for survival, made in this present conflict. Medicine has kept pace with these advances by new research and study on the care of the human body when exposed to the stresses and strains of new and abnormal physiological requirements—in the stratosphere, under the sea and on the surface of the earth. We have learned much of how man must adjust his physiological mechanism to meet the rigors of these strange, new and often terrifying environments. It is not, however, man's body alone that is affected by the rigors of war, it is probably psychologically and emotionally that he pays the greatest toll.

Medicine has accepted the challenge of total war and the great advances which have been made are not only in the scientific and technical fields but also in those of human relationship. The bond between the patient and the doctor has had a rebirth. Thousands of doctors and millions of men are coming out of this war with closer ties than ever before. The science and art of medicine have become welded inextricably to meet the physical and spiritual needs of man.

This has been particularly true in the field of convalescent care and rehabilitation, where a close patient-doctor relationship has become the keystone of the treatment and management of casualties returned from combat theaters. Early in the war when the conservation of manpower made necessary a comprehensive program, in order to reclaim every man possible for the military service, the Army Air Forces formulated a program based on this concept.

In those uncertain days, every man hour of training in the Air Forces was unbelievably important. Our radio schools, mechanics schools and flying schools worked around the clock, twenty-four hours a day, seven days a week. In spite of this emphasis we still had in our military hospitals thousands of men who had completed their definite medical care and now merely sat around waiting for time to complete their convalescence. These hours spent in boredom without any purposeful activity did not contribute to the mission of the Army Air Forces.

*Chief, Convalescent Training Division, Office of the Air Surgeon, Washington, D. C.

THE AAF CONVALESCENT TRAINING PROGRAM

It was in an effort to provide for the purposeful utilization of this hitherto wasted time and to provide a program of activity which would be an adjunct to the definite medical care of the sick soldier that General H H Arnold, Commanding General of the Army Air Forces, in December 1942, ordered that a Convalescent Training Program be established in all AAF hospitals under the direction of Major General David N W Grant, MC, the Air Surgeon, since its inception at that time, over sixty million man-hours of physical and educational training have been given in Army Air Forces hospitals—sixty million man-hours of productive time which would have been wasted. The teaching rate at the present time is in excess of four million man-hours per month.

A Convalescent Training Program is provided for the ordinary sick precombat trainee as well as for the battle casualty. Physical reconditioning is accomplished by a systematic, graduated series of calisthenics and corrective exercise. These are first given in their mildest form even to bed patients. The exertion is gradually increased as the patient's physical tolerance and general condition improves until he is able to participate in a fully organized program of drill, hikes, active recreation and fatigue duties. Exercises begin in bed postoperatively as soon as the patient's condition permits, which prevents muscular atrophy of the unaffected parts and general deconditioning. A pneumonia patient begins deep breathing, hand, arm and chest exercises as soon as his temperature is normal. This simple, early exercise routine not only improves the muscle tone of the patient but is an excellent morale factor.

Designed for a dual mission, the Convalescent Training Program aims, first, to send the soldier back to duty in the best possible physical condition in the shortest period of time, secondly, to teach the soldier-patient something that will make him a more efficient and effective fighting man. Under this plan, physical activity and military education have become as much a doctor's prescription as drugs and diet. Muscles are not permitted to atrophy, for reconditioning exercises start the moment the acute illness or surgery is terminated. Minds do not become stagnant. Time formerly wasted in reading comic books and adventure stories is spent purposefully. The classroom has been moved into the wards, and training films, chemical warfare classes, radio code practice periods and discussions on why we fight and the postwar world have become an integral part of the hospital day. Radios, carburetors and even airplane engines are brought into the wards and the sun rooms. The hospital has been transformed into a combination gymnasium, schoolroom, machine shop and New England Town Hall.

PHYSICAL REHABILITATION

Early in the program it was noted that, to obtain maximum results, reconditioning had to start at the earliest possible moment following acute disease or injury, and it had to be *purposeful* and *progressive*, starting with bed exercises taken ten minutes twice daily and gradually increased to four or five hours a day of physical activity. Special corrective exercises were designed to meet the military needs and experienced physical training instructors assigned to administer them. A positive attempt was made to correlate ward fatigue and detail work with the soldier's disability to aid in functional recovery. Men with hand, finger and wrist injuries were given fatigue duties that involved finger and hand manipulation while those with bad backs or knees were given duties which aided in their recovery by strengthening the affected part. A special booklet, AF Manual No 23, *Handbook of Recovery*,¹ was designed as a prescription blank for all types of orthopedic injuries, a nine-page section on anatomy, physiology and pathology, written in simple language, demonstrating to the GI soldier why he is in the program, the value and effect of active exercise, how bones, muscles and nerves are made, what happens when they are injured, and how they heal, a two-page descriptive prescription for the specific injury, which shows the soldier-patient by diagram the normal function of the affected part, his diagnosis, the type of physiotherapy prescribed, illustrated active exercises to be done with and without supervision, and a personal objective recovery chart which the patient maintains himself. This has been a very effective innovation, as it not only gives the patient an insight into and understanding of his condition but by competing with himself, a greater motivation. An accompanying instructors manual,² AF Manual No 24, *Handbook for Physical Retraining*, has been prepared for the guidance and use of the physical reconditioning instructors in order that they may properly administer and supervise the exercises so as to obtain maximum results.

Another publication which is meeting with widespread approval is the crutch-walking handbook, AF Manual No 49, *Let's Walk*.³ Unique in its presentation, this booklet deals with the functional aspects of walking with the use of aids. It first gives the patient a brief, psychological orientation to his disability and then proceeds to demonstrate objectively through the use of illustrations and charts the factors involved in walking with aids, the muscles which must be utilized and therefore strengthened to use walking aids effectively, the techniques and gaits of walking, practical hints on the care of the aids, and, most important, insight and motivation.

End Results—More interesting, however, and perhaps more than the means used to meet our objectives, are the ends.⁴ The experience with the Convalescent Training Program twenty-eight months has contributed some interesting the pertinent observations are that

- 1 Hospitalization time has been shortened,
- 2 Hospital readmissions have been reduced,
- 3 Sick leave has been practically eliminated except in extraordinary cases,
- 4 The morale of the soldier-patients has been immeasurably improved, for they have been kept interested and busy in purposeful activity

A number of interesting clinical studies have been made Van Ravenswaay and his co-workers⁴ studied 645 patients with virus pneumonia, treated in one acute ward They were then assigned to alternate convalescent wards In Ward I, "nature was permitted to take its course" men sat around and went back to duty when they and the medical officer felt they were able In Ward II they were kept in bed until their sedimentation rate had reached 10 mm in one-half hour and they were then put in a reconditioning program, beginning exercises for one-half hour the first day and increasing progressively until the twelfth day, when the patient was participating in a full six-hour day of physical training, mass games, competitive sports and active recreation, including a 10-mile hike Group I averaged forty-five days of hospitalization, with a 30 per cent recurrence rate, Group II, at the end of thirty-one days, was discharged to duty, with but a 3 per cent recurrence rate forty-five days' hospitalization, unsupervised, thirty-one days with graduated conditioning—a 30 per cent recurrence rate compared with a 3 per cent recurrence rate

Karpovich and his associates at the School of Aviation Medicine, San Antonio, Texas, have studied a similar group of 200 aviation cadets convalescing from virus pneumonia⁵ Using a modification of the Harvard step test and starting as early as the first afebrile day, Karpovich found that by the reactions to this test it was possible to determine, with a degree of accuracy, the patient's ability to enter into, and the degree of participation in, the Convalescent Training Program activities An interesting by-product of Karpovich's observations was that patients being tested required an average of five days less hospitalization time than those participating in the general program, which certainly points to the fact that these men can tolerate an even more strenuous reconditioning program

Colonel Gilbert Marquardt, MC, Chief of the Medical Service at the AAF Regional Station Hospital No 1, Coral Gables, Florida, has recently made an interesting observation on a small group of patients recovering from virus pneumonia⁶ These patients were clinically well but still had definitely positive x-ray findings They were put on hyperventilation every waking hour, twelve times a day, and serial x-rays were made every twelve hours Over 90 per cent of the patients in this series became x-ray clear in a period of ninety-six hours Further studies are being made at this station, having the patients hyperventilated even during the febrile stages of the disease to

determine if such a procedure will aid in the prevention of patchy atelectasis

Early in the operation of the AAF Convalescent Training Program it was noted, clinically, that orthopedic patients requiring fixation of a specific member did not, if kept in top physical condition generally, show the usual degree of muscular atrophy in the fixed part and that when the cast was removed, they could be reconditioned to duty in approximately one-half the usual convalescent time. This has saved a tremendous number of noneffective man hours for the Air Forces. This clinical observation certainly gives food for further thought and physiological study.

Physical Fitness Testing and Physical Training of Convalescent Rheumatic Fever Patients.—As a part of the AAF Rheumatic Fever Control Program,⁷ Karpovich, Weiss, Starr and Ershler have recently presented a preliminary report of their work on physical fitness testing and physical training of convalescent rheumatic fever patients.⁸ Because of the chronic, recurrent nature of the disease and the possibility of disabling cardiac sequelae, it was felt that special emphasis must be placed on standardization of physical activity and convalescent training for these patients through building a group of graduated physical fitness tests which could be used in conjunction with clinical observation to determine the rate by which the patient could safely be permitted to progress to successively more strenuous physical activity. Using a modification of the Harvard step test with two benches 12 and 20 inches in height and a cadence of twenty-four steps per minute, physical testing was started when, in the judgment of the medical officer, the patient should be permitted to be out of bed in a chair. The first test involved twelve step ups in thirty seconds, using the 12-inch stool. Criteria for passing the test are a pulse rate less than 100 per minute one minute after the exercise and good coordination in the performance. If the patient passed this test and the medical officer concurred, he was allowed to be ambulatory in the ward. Using the same criteria the next test involved twelve step-ups in thirty seconds, using the 20-inch stool. In this test it was found that body metabolism in the average individual was raised eight to ten times. If this test was passed the patient was placed on a program of graduated ward calisthenics. These exercises were given for ten minutes twice daily to start, and over a period of approximately three weeks, they were then increased to thirty minutes twice daily. The exercises used at the start of this program have been found to raise body metabolism roughly three times. The degree of the exercises during this period was gradually increased to a level which raised the metabolic rate seven to nine times above normal.

The next level of physical fitness testing was designated the progressive test, consisting of twenty-four step-ups per minute to a 20 inch bench for a period up to five minutes. Scoring was based on the

duration of the exercise plus the pulse rate one minute after exercise. If the patient made a minimal passing score on this test and the medical officer in charge concurred, he was placed in the barracks phase of the program with a minimum stay of two weeks in each of four periods. In the first period, physical training was given for forty minutes daily, in the second phase, fifty minutes daily, in the third, seventy minutes daily, and in the final period, for ninety minutes. The intensity of the exercise was increased in each period and progressions were made only with concurrence of the medical officer in charge. Progressions from period one to period two were automatic after two weeks, but progression from period two to period three was dependent upon the score made on the progressive test. To date, approximately seventy patients have been used in the study with no recurrences or other untoward reactions.

Some five thousand patients of all types have been studied on their day of discharge from AAF hospitals with the standard AAF Physical Fitness Test, consisting of chin-ups, sit-ups and running against time. These patients averaged approximately 3 per cent better scores than the average made by troops on duty status at the same bases. It is felt that this is evidence of the fact that, following the hospital's Convalescent-Reconditioning Program, men are being returned to duty *ready for duty*.

The Undesirable Effects of Bed Rest—During the past year there has been tremendous interest in the physiological and psychological problems of bed rest, and already material is accumulating in the medical literature in this field, with many additional studies currently being carried on.⁹ Keys,¹⁰ working with conscientious objectors and studying them under carefully controlled conditions of complete bed rest for six weeks, in his preliminary observations has noted that these individuals' reaction time is reduced approximately 5 per cent, that coordination is markedly decreased, especially in the proprioceptive senses, that blood volume is reduced from 10 to 20 per cent, and there is a reduction on an average of 11 per cent in the size of the heart. He noted that in the standard work test, after a period of bed rest, there is a reduction of cardiac effectiveness with a relative tachycardia, both at rest and in work tests, work formerly done with a pulse rate of 125, on the first day after prolonged bed rest would often cause the pulse to reach 170. He noted further that it takes a period up to sixty days to recover normal pulse rate for the same work load. A mounting pulse rate even at complete bed rest under basal conditions was also observed, pointing to the increasing incapacity of the heart to maintain the circulation adequately. Keys also noted that it is very difficult to keep a patient in positive calcium balance, especially during the early days of bed rest, and that more than twice the amount of protein in the diet is necessary to keep the patient in normal nitrogen balance. There

is also a marked increase in the urinary output of thiamine and riboflavin

Clinical and laboratory investigations now under way point toward the necessity for a broad research program in this whole field and a better understanding by the medical profession of the deconditioning-reconditioning phenomena of the individual who is confined to bed

EDUCATIONAL RETRAINING

The second aspect of the AAF Convalescent Training Program for the precombat soldier-patient is a teaching program designed to increase his military knowledge and make him a better soldier. The educational program is designed to meet the needs of all special types of Army Air Forces installations. In basic training centers, the emphasis is on self-protection, gas warfare, camouflage, booby traps, map reading, care of equipment and medical aid. All types of training, orientation and morale films are used daily. Training aids, visual aids and handicraft, with model airplanes, tanks, ships and camouflage nets have proved of excellent educational and corrective therapeutic value.

Special classes have been organized both for the teaching of men educationally retarded and giving instruction in subjects such as mathematics and physics for patients scheduled to take later air crew or technical training. A daily summary of current affairs and an orientation course in military geography are a part of all curricula.

In the technical schools the program is modified to meet the special needs of the patient. At the radio schools, special code receiving sets and sending keys have been placed in the hospital wards so that men may continue to increase their skill even while in bed. During certain periods of the day the wards are blacked out and the men send and receive blinker code from bed to bed. Formerly it was noted that men would lose their code speed after a week without practice. Now our patients are leaving the hospital with maintained and, in many cases *increased* speed.

In the hospitals serving the flying schools and tactical units, geography, geopolitics, airplane identification, reptile-insect-pest control lectures, lectures on arctic and tropical medicine and field sanitation are the subjects stressed. Medical officers have designed a series of patient-doctor talks to give the men a knowledge of the symptoms, cause, treatment and prevention of various tropical diseases. This has been of tremendous help in orienting these soldiers to their new environments and allaying the fear that comes naturally when going into unfamiliar surroundings.

ROLE OF THE AAF CONVALESCENT HOSPITAL

Based on observations of the medical, physical, psychological, vocational and social needs of men returning from overseas combat and a realization that the Convalescent Training Program as carried on in

AAF regional and station hospitals was not designed to meet these specialized needs, special AAF convalescent hospitals were activated on September 18, 1943. Originally known as convalescent centers and subsequently renamed "convalescent hospitals," they were at first attached to existing operating facilities but as the increased need and desirability of operating such facilities as independent units became apparent, the convalescent hospitals were relocated, often taking over entire army posts.

Operated by the AAF Personal Distribution Command, these hospitals provide convalescent training programs designed to meet the needs of the *whole* man, whatever they may be. Patients are admitted to these hospitals from ASF general hospitals, AAF regional and station hospitals upon completion of definitive medical care, directly from airports and seaports of debarkation, and from AAF redistribution stations, if in need of rehabilitation. Every skill and effort is centered on the task of reconditioning as many men as possible in the following sequence of possibilities:

- 1 Return to an AAF assignment in original military occupational specialty,

- 2 Return to an AAF assignment in a new military occupational specialty compatible with civilian and military education and experience and physical condition,

- 3 Return to civilian life as self-sufficient individuals, both socially and economically,

- 4 Discharge to the Veterans Administration.

Program for the Soldier-Patient Who Is to Be Reactivated—For the soldier-patient who is to return to duty status there is an intensive program of physical rehabilitation, educational retraining, psychological readjustment, and resocialization. Men are brought to the peak of physical fitness through competitive team play, progressive and graduated calisthenics, and active recreation, which includes athletics, bicycling, horseback riding, fishing, swimming, hiking and skiing. Military training is provided for further specialization in the majority of military occupational specialties applicable to the Army Air Force. In addition to class and individual instruction in such subjects as administration, clerical training, supply, teletype operation and repair, radio code, graphic arts, navigation, Link Trainer, gunnery, aircraft mechanics, automotive repair, canvas and leather work, electricity, aircraft instrument repair, machine shop practice, photography, radio operation and repair, sheet metal work, welding and woodworking, practical experience is provided by "on the job" training in these subjects.

Patients also have opportunities to enroll in numerous academic classes, shop classes and hobby groups. Through the United States Armed Forces Institute and nearby local educational institutions, many of these courses can be taken for high school and college credit. Jour-

nalism, radio broadcasting, dramatics, art, handicrafts and many other avocational activities are more than diversional in that they provide the media, along with well-rounded and complete recreation programs, for psychological adjustment and resocialization.

Psychological Readjustment and Resocialization—A well-rounded and diversified program aimed at psychological readjustment and resocialization is of prime importance when dealing with patients returning from combat theaters. Any man returning from combat must make a great adjustment, both physically and emotionally. There is an obvious endocrine imbalance in the men who have lived in "condition red" for weeks, months, and—sometimes years! Most of these men returning from combat are fatigued to the nth degree, both physically and mentally. They must have sufficient time and understanding care during this period of human conversion from wartime to a peacetime status.

When a man enters the army he is thrown into an entirely new environment and loses contact with many of the environmental influences which have been controlling factors of his behavior. He no longer comes in close contact with many of the social institutions familiar to him with civilian life. His attitudes, habits, concepts and values during civilian life were built largely on his day-to-day associations with these familiar institutions of social life. In the army he no longer comes in close contact with these social institutions and he, therefore, is forced, because of factors in his new environment, to adopt a new set of attitudes, values, concepts and habits. When he leaves this country to enter a theater of operations, because of military necessity the distances involved cause his contacts with these stabilizing factors to become even less and as a result, those attitudes, values, habits and concepts are altered by the environment and mores of his even more restricted fields of interests.

The Army has done a splendid job in keeping the man in combat linked as closely as possible to the home ties. Our improved mail systems, communications, orientation programs, wide use of movies and similar factors have made home seem much closer to the fighting man of today than to the soldier of twenty-five years ago. But Aachen, Leyte and Bologna are not Cleveland, Pasadena and Kansas City. The environment is different, the life is different, the daily objectives are different, and it only follows that a man's thinking, behavior, concepts, ideas and values are different. When a man is wounded in combat and goes to the hospital, there is usually a temporary psychological relief, even though his wounds may be serious, due to the fact that he is alive, is out of combat for the present at least, however, new problems present themselves—problems that involve his whole future. He loses contact with the men with whom he has lived and fought in close association; the men who have to a large degree replaced his civilian associates. Regardless of the fine medical care that the casualty receives,

he is changed by his army experiences, he is a different man than he was before combat, different than he was before he was wounded. He is not necessarily a psychiatric casualty. His mental and moral fiber may be as tough or even tougher than before, but he has been out of touch with the normal activities of his normal civilian life. His attitudes, values and habits, of necessity, have changed. The restoration of these attitudes, habits, values and concepts accepted by American society must be a part of his medical treatment. By providing the soldier-patient with a laboratory of opportunity through physical reconditioning, educational-avocational pursuits and recreation he will regain those traits compatible with normal behavior patterns. By stimulating interest and motivating the patient to participate in such activities his center of interest is transferred from himself to the activities in which he is participating, with resulting adjustment and resocialization.

In an AAF convalescent hospital each patient is assigned to a personal physician who becomes his "family doctor" for the period of his hospitalization. This personal physician has a paramount place in the AAF convalescent hospital. He is the captain of the team of medical specialists, physical therapists, educators, athletic trainers, occupational therapists, social service workers, personal counsellors and vocational guidance experts, and as such, integrates their efforts in the treatment of the whole man.

The latest in physical rehabilitation technics, use of prosthetic devices, teaching of factors inherent in daily living, and skills needed by those who have physical and psychological wounds are available. All personnel have been carefully selected on the basis of experience and demonstrated ability, and many have taken special courses at the Institute for the Crippled and Disabled in New York City and at seminars conducted by the Office of the Air Surgeon and the AAF Personnel Distribution Command.

A special program has been developed in the Army Air Force for combat casualties suffering from *operational fatigue*. Pioneer work was done in this field by Grinker and his associates.¹¹ Hastings, Murray and Wright¹² have also added to the knowledge of this condition and its diagnosis and management. As an adjunct to this definitive psychiatric care, the AAF Convalescent Training Program, through its directed activities, has proved of value in the emotional adjustment of these patients through a program of planned physical activity, competitive sports, and nonconcentrative types of teaching. The great majority of men suffering from operational fatigue so treated are returning to duty in the Army Air Force.

Program for the Soldier-Patient Who Is to Leave the Service—For the men who are to be separated from the service there is, in addition to the physical reconditioning, educational training, psychological rehabilitation and resocialization opportunities, a complete program of

vocational guidance based on achievement, aptitude and functional testing and interests determined by a series of short work experience. In these short work experience under a staff of experienced vocational instructors, the patient has an opportunity to participate in a diversified educational program embracing academic subjects, commercial skills, photography, art woodworking, metal shop, welding, machine shop practice, automotive repair and a host of similar fields. The man learns not only what he likes to do but he learns what he is able to do, both in terms of ability and in terms of any handicaps he may have. He knows at the end of this period what he enjoys doing, what he is able to do and the occupations for which he possesses aptitudes. This information is correlated by a skilled vocational counsellor with the job opportunities in the field chosen, and the patient upon discharge from the hospital has a complete objective vocational profile.

At this point the community and appropriate governmental agencies, notably the Veterans Administration, must take over. It is the mission of the armed services to retain these men in the service until they have reached maximum hospital improvement, which includes all of the rehabilitative procedures that have been described, and to send these men back to the community as motivated individuals, eager and ready to take their place in the community life of a democracy. It is here that the community must take responsibility for aiding these men in living a self-supporting, self-respecting life. There is a great need for a broad educational program at the community level so that labor, industry and the relatives and friends of the returnee will understand, in some measure, his problems and how they can help him to meet them. Time, sympathetic understanding, and patience are the primary requisites.

Much has been written on the subject of the reception of the disabled soldier. If we remember that the primary rule is "IT IS THE MAN AND NOT THE DISABILITY," and we look upon him as such and use the simple rules of good manners and common sense, the problem is readily solvable. The civilian physician who is going to take over a large part of this load must aid in the broad, civilian educational program so that the civilian population will understand what happens physically and emotionally to the man returning from the wars and how to meet the problems involved.

POSTWAR IMPLICATIONS

The experience gained in convalescence and rehabilitation in military medicine presents new opportunities in civilian practice, postwar. Rehabilitation is not primarily a military problem. Eleven thousand men were wounded in the first ten days after "D Day." During that same period of time, over 25,000 civilians were injured in the United States in automobile accidents alone, even with gasoline rationing. It has been

estimated that there are 800,000 incapacitating accidents occurring each year in the United States. There are between 3,000,000 and 5,000,000 physically handicapped citizens in this democracy who are in need of some type of physical rehabilitation. War only focuses the spotlight of public opinion on this great national problem.

There is a great need in this country for a planned program for the patient to fill the dead space between acute illness and the ability to return to a productive occupation. A typical case in civilian life in one of our large city hospitals will illustrate this point. A 50 year old male, a high line electrician employed by a large utilities company, enters the hospital with his first cardiac breakdown. He is examined by the resident staff and the diagnosis of degenerative heart disease with decompensation is made. The diagnosis is checked by the visiting physician and proper treatment instituted. After a short period of time his heart is compensated and, following a brief period of rest, he is ready for medical discharge, usually with this advice: "Here's your medicine, take it regularly, as directed, and report back to the clinic in two weeks. You know, of course, that you will never be able to do any strenuous work and you cannot continue with your job as a high line electrician." If we stop there, the bottom drops out of this patient's world, he says to himself: "*I can't stop working, I have children in high school, my house isn't paid for, my insurance won't be paid up until next year, all I know is an electrician's work on the high line I have to work!*" And he disregards the doctor's advice—and dies. Or, he reports to his employer and asks to be retired on a pension, if he is eligible—a physical and psychological cripple, his living standards reduced 50 per cent, his buying power decreased 50 per cent—an unwilling liability to himself, his family, and to the economic structure of his country. This *must* be avoided.

The doctor alone, however, is not responsible for the solution of this problem. Labor and industry must play an active part in solving this man's problem, in salvaging him for some type of productive work within his physical capabilities, and a rehabilitation program must be set up to meet this need. If a representative of labor and industry, a skilled vocational guidance expert, could go to this man early in his hospitalization period and say: "I represent your company and labor. You are not going to be able to continue with your old job, with this type of cardiac disability, but there are fifty jobs in your company that you *can* do and we will start right now in the hospital on your retraining for a new job," the problem would soon be solved. A rehabilitation program that starts at the bedside and follows through to purposeful placement! If such a program were established, the patient would retain his self-respect and ability to be self-supporting, industry would save the required pension, labor would save a valuable workman, democracy would retain its economic level. Such a program be carried on with proper teamwork—medicine and all of its allied

sciences working with labor and industry to care for the man *as a whole*

Rehabilitation Centers, established at key points, working both on an in-patient and an out-patient basis, with direct association with hospitals and offering a program of physical and mental rehabilitation, vocational guidance, with opportunities for short-work experience and vocational testing, and, for the more severely handicapped patients, a sheltered workshop, would reclaim a large percentage of these unfortunate individuals from hopeless dependents to proud, self-sustaining individuals

The growing interest in the field of *physical medicine* opens a great, new field in rehabilitation first, physical medicine as it pertains to definitive treatment and its utilization in the diagnosis and treatment of disease, secondly, physical medicine in its broadest sense medicine in its relationship to environment, occupation, social status, and in the specific field of individual rehabilitation, utilizing as the basis the greatest physical potentialities—the potentialities of oneself, the *science* of retraining and utilization of these potentialities and the *art* of such application.

Hospitals must be made into institutions of opportunity The average patient in the hospital suffers but 10 per cent of the time and is bored to death the remaining 90 per cent. The hospital must take its place in the community with programs that aid the patient in his re-orientation back to normal living Occupational therapy, prevocational therapy, vocational guidance, and opportunities to broaden the patient's knowledge in his field of work, geography, languages, literature, and interesting short courses in problems of daily living, should be made a part of the hospital routine Hundreds of interesting films and slides are available through the various agencies and foundations and may be obtained by the asking They could be shown daily in the hospital wards All types of literature on foreign affairs, living in a democracy, homemaking, avocations and hobbies—all are available readily Convalescent patients with talent are an ever-available source of teachers and lecturers, and all types of civilian organizations are available to organize and implement—even take over—such programs in the community if they are shown the need for, and the potentialities of, such a program Sporadic programs of this type have already proved to be eminently successful, and if this new concept became endemic, it would have a tremendous bearing on the social life in this democracy and would greatly strengthen the keystone of medical practice—the patient-doctor relationship

Our medical schools and their faculties must meet this great challenge and include as a major part of their curricula the practical relationship of disease to economic, social and environmental factors The young physician must be made to realize that treatment of disease is only a *part* of his problem, he must also treat the *patient* The phys-

ician must know the *science* of medicine but practice the *art*. To meet the challenge of rehabilitation there must be a group of specially trained physicians who know disease and disability in its relationship to the economic, social, vocational and environmental factors, who can "captain" a team composed of specialists trained in the ancillary sciences—physical education, social service, occupational therapy, vocational guidance, psychological testing, and physical medicine. This physician would be a specialist in the field of *orthergasia*, which literally means "conditioning for normal function and adjustment." Normal function and adjustment—the goal of rehabilitation.

PSYCHIATRIC DISORDERS IN COMBAT CREWS OVERSEAS AND IN RETURNEES

LT COLONEL ROY R GRINKER
MEDICAL CORPS, ARMY AIR FORCES

PSYCHIATRIC disturbances that result from exposure to the stress of combat we term war neuroses. In the Air Forces we use the euphemism "operational fatigue," an inheritance of peacetime aeronautics, as a convenient disguise for those who find the term "neurosis" unpalatable. This does not signify that fatigue itself is all-important as a causative factor nor that fatigue is a frequent symptom. I propose to discuss these war neuroses as they appear overseas in combat and as they are evidenced in this country among returnees. The latter group are of more interest to this audience since they closely approximate the problems that all physicians in the military service and civilian life will encounter among men who are separated from the services with medical discharges or are demobilized at the end of the war.

PSYCHIATRIC DISTURBANCES IN WAR THEATERS

Interacting Factors in Their Production—To understand war neuroses one must know what internal and external factors interact in their production. They depend on the relationship of determinable forces such as the individual's psychological predisposition, his motivation and training and the morale of his unit, on which indeterminable accidental factors of stress operate.

The Individual's Psychological Predisposition—Obviously the reaction of the man himself under stress carries with it the coloring of his previous personality. In the Air Forces we have special psychiatric screening processes which are fairly successful in rejecting men with overt neuroses from flying training. It is not so easy to detect latent psychoneuroses or personality trends which predispose soldiers to react with war neuroses early in combat. We have found that men with psychosomatic disturbances, that is, functional visceral troubles, are almost certain to react quickly under stress with an increase in their symptoms. Compulsive-obsessive characters do not do well since their ritualistic defenses quickly break down, uncovering anxieties and depressions. Furthermore, people with depressive characters react badly to the loss of comrades and usually succumb to long-lasting melancholia. There are certain general personality types predisposing to early breakdowns, among which may be mentioned the extremely passive and dependent person constantly expecting injury to himself.

From the AAF Convalescent Hospital, Don Ce Sar Place, St. Petersburg Florida.

the overcompensated, tough individual who has never experienced subjective anxiety, and the schizoid person who is rather seclusive and difficult to get along with and who uses flying as a means of escape from close interpersonal relations. All these characteristics and latent tendencies are so ubiquitous that it is almost impossible to weed them out. Yet it is a matter of chance as to whether the stress will become severe enough to precipitate them into a neurosis.

Recently we have heard criticisms of the numerous rejections for psychiatric causes. It is contended that if a boy is willing, the Army should take him and through strict discipline and training make a man of him. That is a sure way to slow the war effort and ruin these boys. Army life and certainly combat is a tough business and, as I shall point out later, causes more psychological regression than growth. Psycho-neurotics well adapted to some form of civilian life should be undisturbed in their adaptation or at best used only for some special army task in a particularly favorable environment. This is not a theoretical postulate but is based on practical experience.

Motivation and Training—Another aspect of the man himself is his motivation. There are many individuals who have strong motivation for flying but not always of a healthy type. The man who flies to get away from people, from earthly problems, or to overcompensate against his feeling of weakness on the ground, does not have a healthy motivation. This is more likely to be the initial result of strong identifications with firm but kind father figures and later with the strong and respected leader of the group.

Good training and confidence in his ability is a fortification that often protects the soldier against overwhelming anxiety while under severe stress. Lack of confidence in one's ability is often an important predisposing factor in creating excessive and uneconomical anxiety.

Personal and Group Morale—In modern warfare, combat is carried on in relatively small groups into which men are integrated as early as possible in training. The individual's relationship in the group as a brother to all the other men and as a son to the leader is important in establishing good morale which is the most essential protective armor against war neuroses. Morale is not the result of subscription to high-sounding ideologies or ideals of which there are relatively few in this war. That type of morale may function when one's country is attacked and one's family and friends are persecuted or tortured but even the Russians have plenty of war neuroses. But for our Army, war is a dirty business and simply a task that the soldier must finish as soon as possible in order to return home.

The best morale that can be expected depends on a good interpersonal relationship within the group. In such a setting the soldier loses his individuality, correspondingly his weaknesses, and assumes the strength and fearlessness of the group confidence in its ability and its

The leader must, of course, be strong enough to inspire con-

fidence, be fair and equitable to all his sons, and have a reasonable amount of courage himself. When morale breaks down because of disturbances in leadership, the individual quickly crystallizes out of the group solution and becomes an individual again, filled with anxiety concerning his own self-preservation. In this state he is on the way toward the development of a neurosis. The same thing happens as he leaves the group after an honorable tour of duty or is rotated home. He then becomes an individual and may even develop an anxiety state as he thinks of himself as a person in retrospect, recalling the dangers he experienced and the near catastrophes that he escaped.

Impinging Stresses of War—The stresses that affect an individual are those stimuli that disturb his particular character structure and break down his protective devices against anxiety. These stimuli are unpredictable and may in one case be minimal and in another be extremely harrowing. The stress is not always the danger of combat. Poor living conditions, bad food and inclement weather are among a host of other stresses that weaken the ego in its capacity to endure the anxiety stimulated by traumatic experiences. In fact, it can be stated that even more important than the effects of flak and bullets on the flier are the disturbances of close relationship with comrades in the group. The visualization of another plane being blown up, the loss of a close buddy, the loss of the soldier's ship with all the other members of the crew, are among many serious situations that create profound neurotic reactions.

From the preceding we can see that the factors of the individual's innate psychology, his training and confidence, his personal and group morale and the stresses which impinge upon him, are all important in determining the rapidity with which he succumbs to anxiety states, and their severity. From these data you could have anticipated our experiences in the theater of operations. We found that no matter how strong or normal or stable a man might be, if he had to endure stress sufficient to reach his personal threshold, he would succumb to a war neurosis. Man's threshold is variable and a stereotyped performance from each human as from an airplane engine could not be expected. Furthermore, many men with chronic anxiety states were able to endure combat without any great accretion to their subjective disturbances. These people were accustomed to anxiety and a trifle more of such distress was not too disturbing. They also often felt better when they could attribute their neurotic inner anxiety to external events. When this happened they became as normal as the others.

Types of Neuroses Seen in Combat Crews Overseas.—Anxiety—The most common type of war neurosis seen overseas is characterized by the subjective sensations of various quantities of free anxiety and objective signs of sympathetic overactivity. The fliers become irritable, restless and sleepless with catastrophic nightmares of battle. They develop tremors, severe startle reactions, tachycardia, loss of weight

and excessive perspiration. The anxiety state is apparent on cursory examination. There are gradations in this condition from the beginning stages in which a man shows early personality changes, loses confidence in his ability and is reluctant to go on missions. At this time he declines to talk about combat and hesitates to consult his doctor because of a misinterpretation that his condition is one of weakness or cowardice which he strenuously fights. Yet it is in this phase that therapy is most effective. The proper utilization of a rest camp for four or five days, temporary relief from combat, good food, reasonable comfort and sufficient sedation to produce sleep, often strengthen the ego sufficiently to enable it to endure more anxiety. As the process continues the individual becomes more anxious and develops phobic reactions in that he is frightened of a particular type of plane, enemy fighters, flak, bad weather, and a host of other external dangers. He may continue to fly in this stage but his abilities are markedly reduced. The pilot may become inept at the controls and handle his plane badly, or the crew members may freeze at their guns and not be able to shoot at the approaching attacking plane. Finally, the man becomes so seriously ill with anxiety that he is unable to get into the plane at all, in fact often cannot even fly as a passenger in a safe and secure transport. At this stage he must be grounded and given definitive psychiatric treatment.

Depression—Many soldiers develop depressions. This emotion is almost always present when a man is ill with anxiety and has to be removed from combat. He has guilt feelings and self-depreciation because his ego-ideal interprets his illness as a sign of weakness. Furthermore, many men go into a serious depression over the loss of close friends which they attribute to some omission or commission on their own part and hold themselves responsible for the tragedy. These feelings of guilt and depression are usually related to the fact that toward the lost comrade the patient has had both hostile and affectionate feelings. It is the repressed hostile feelings that are responsible for the strong feelings of guilt and depression.

Psychosomatic States—Psychosomatic states develop, of course, early in those who have had them in the past. However, in almost all combat neuroses some psychosomatic disturbances develop as the tolerance of the ego for anxiety decreases. The most frequent symptoms are referred to dysfunctions of the upper gastrointestinal tract. Such symptoms as nausea, vomiting, indefinite abdominal pains or severe anorexia are typical. We rarely see the disturbances in heart function that were so frequent in the last war.

Psychosis-like Disturbances—Another frequent type of disturbance occurs in combat and resembles certain psychoses in that the individual's ego has lost its power to discriminate dangerous from safe reality. The whole world becomes a hostile dangerous place to which he constantly reacts with apprehension. Or he may regress into an

apathetic, dull, almost schizophrenic state. He may become paranoid and believe that all people including his friends and comrades are hostile to him. There may occur a severe dissociation of his personality in that the memory of a severely traumatic situation or the emotional concomitants are repressed into his unconscious, causing a partial amnesia.

Prophylaxis—The prophylactic treatment against war neuroses includes successful selections of men and their maintenance with proper treatment by the flight surgeon. The most important part of prophylaxis is, of course, to maintain a good group morale which is a function of command assisted by advice from the medical officer. The early treatment of neurosis is rest and psychological support to strengthen the ego forces which repress anxiety, and this is successful only when physical fatigue and psychological exhaustion are important factors in the etiology. When these methods are not successful the flier must be grounded and referred for definite psychiatric care. For the severe cases recovery cannot be accomplished in a theater of operations in a brief time. Therefore, most of these men are sent to the United States for rehabilitation. Once a man has developed a definite neurosis rehabilitation overseas is successful only in bringing men back to a condition in which they can return to reclassified duty. Only rarely is it possible to send them back to combat.

PSYCHIATRIC DISORDERS IN RETURNEES

Etiology—The Army Air Forces have made provisions in this country for the adequate treatment of returned combat troops suffering from "operational fatigue." However, the majority of admissions to the hospital are not men who returned home with war neuroses but those who developed signs of sickness after completing a full tour of duty. Their symptoms developed or increased after release from combat, during their furloughs or while anticipating reassignment. There are a number of possible explanations for this fact. Some men had mild neuroses which they held under control as long as there was a purpose for so doing, but after completion of combat their ability to suppress symptoms failed. Anticipation of returning to combat after furloughs may be the last straw of anxiety added to the load which the ego has already had to bear so that the man develops a neurosis. It sometimes happens that the weakened individual is disturbed because he had returned to a home situation which is unsettled and conflictual to him as it has been in the past. Finally sometimes the soldier has been so changed as a result of his combat experiences that he cannot adjust to living in even the most favorable environments at home or in the United States. All these factors have their share in the production of war neurosis in returnees. We frequently say that the neuroses produced by combat are the result of abnormally severe stresses impinging upon a relatively normal personality. We can reverse this axiom

and state that war neuroses that develop at home are the result of the difficulties of a changed personality to adapt itself to relatively normal environmental circumstances. It is this type of patient that we all will have to treat long after the war has ended.

Symptoms—Among the most frequent symptoms of "operational fatigue" in returnees are restlessness, irritability or lethargy, insomnia, battle dreams, loss of weight, signs of sympathetic overactivity, alcoholism, startle reactions, subjective anxiety and depression, anorexia, upper abdominal pain, nausea and vomiting, aggressive and hostile behavior, paranoid reactions and mental confusion. These are the major symptoms of war neuroses developed overseas, during or after combat, as well as the neuroses that manifest themselves in returnees. In the latter, such symptoms are usually milder.

Classification—Almost every returned combat veteran has a certain degree of physiological and psychological disturbance, but these unwind or uncoil within the course of relatively few weeks time. The abnormal reactions persist despite time, rest or any other procedure except definitive psychiatric care. No one symptom or group of symptoms is characteristic of a particular syndrome, yet we can classify people as to the leading psychological trend which they reveal on closer analysis of their problems. We are able to divide them in spite of considerable overlapping, into (1) the passive-dependent reactions, (2) the hostile-aggressive reactions, (3) the depressions, (4) the psychosomatic reactions, (5) the psychotic-like states.

Passive-Dependent Reactions—The passive-dependent individuals who form the largest number of our sickest returned soldiers may express this trend overtly and in doing so they resemble small children. They long to get home to mother or wife and be taken care of as a baby. They are unable to withstand any deprivation and complain that even the best treatment is restricting. Under pentothal they cry and sob as they relate the terrible things that have happened to them and how they have done all that they possibly can and now it is time for them to go home. In the purest form these people have no self-respecting remnant to their egos that can cooperate therapeutically. However, there are other types in which there is some defense against this regressed dependency. These individuals may express their needs only by excessive drinking. Some of them talk about going home to take care of their parents or families, turning around their great needs as if it were others who needed help and attention. Occasionally we find an overcompensated individual who aggressively attempts to deny his dependency. Some of these boys seek for mother substitutes in rapidly contracted marriages. In many there are associated gastrointestinal symptoms. In all of them there is considerable hostility directed against the Army. The Army represents the cruel father who will not let the boy return home to mama. But in addition, the hostility that was well repressed in the group situation in combat now is released

and no longer displaced toward the enemy but toward the authoritative figures that are responsible for all the bad happenings in combat. It is like a little child who stumbles over a chair and hurts itself, looks up and accuses the first human adult figure with the cry "see what you made me do!"

The passive and dependent group is a mixture of persons whose personalities had reached varying degrees of maturity. Many had never attained any great degree of independence, while others have regressed under the impact of stress. The latter offer the best prognosis for recovery. Many youngsters who had not had time in life prior to combat to attain any ego confidence that accompanies maturity, may use their achievement in retrospect in subsequent therapy. Some of these dependent youngsters suffer from what we have called the *syndrome of ego depletion*. They have given out in independent and aggressive behavior far beyond their capacities, without replenishment to them through affection or love. In this state of psychological bankruptcy they need to rebuild a reservoir of ego strength through the accretion and replenishing effect of being loved. In so doing they resemble children in a stage of development when such an overwhelming intaking process is normal for their chronological ages—children who want everything, who want love and attention, but themselves love only those who give, and turn with rage on those who deprive.

It is this dependent yearning that constitutes our greatest social danger from the veterans of combat who demand rewards as symbols of gratification. Such rewards must be kept up perpetually, for dependent hungers are insatiable. The large numbers of these personalities bring to us a huge therapeutic problem.

Hostile-Aggressive Reactions—The hostile, aggressive individuals may be sullen and negativistic. They are unruly and incapable of obeying the minor discipline of the hospital. Under the influence of alcohol they become wildly aggressive, attacking civilians and fellow soldiers who have not been overseas. Often this behavior compensates against a passive trend. Sometimes it is a means of attaining the attention of the doctors and nurses around them. Often enough it is a need to receive punishment because of guilt feelings related to happenings in combat for which they hold themselves responsible. The majority, however, are extremely aggressive because the goal of their hostilities has been taken away from them. They are no longer able to express their aggressions against the enemy. Their personalities regressed by incorporation into groups and through the stress of combat have lost their internalized ego ideals and there are no inward checks against aggression. The only forces counteracting these trends are external. In the normal course of events the personal and civilized standards of conduct are soon reestablished. When such ego-ideals were originally weak there is a lengthy period of unsocialized conduct often becoming pathological. Correspondingly we have observed that not kindness

and leniency but a temporary firm and strict attitude is productive of the greatest amelioration of this hostile reaction, succeeding far better than persuasion or rational arguments

Psychosomatic Reactions—Psychosomatic symptoms are for the most part related to the upper gastrointestinal tract. Diffuse pain in the abdomen, pain related to food taking, nausea, vomiting and anorexia are among the most frequent complaints, with no positive x-ray or laboratory findings. Most of these patients are only able to ingest milk, vomiting all solid food. They all have considerable anxiety but attribute this emotion to their symptoms. Analysis of the underlying trends also reveals that these patients are not at all conscious of the meaning of their symptoms even though anxiety has spilled into consciousness. The symptoms are indicative of a severe regression to an infantile level, the trends of which cannot reach the level of thought, verbalization or somatic behavior. Some patients express their great need for love and affection by increased activity of the primary intaking organ, the stomach, whose filling the infant connotes with satisfaction. Thus it is only milk that can be retained, an essentially infantile food. Others who feel as if there are weights on their stomachs have a great quantity of repressed hostility which can only be expressed at a low visceral level and they often vomit as the child does so readily, in an infantile way of expressing aggression. When the effect which is part of such "lower level" emotional expressions is made conscious through the use of pentothal narcosynthesis, the symptoms rapidly disappear, indicating their negative relationship to conscious feelings.

Depression—Depressions are usually related to a personal loss. This may be a superior officer, buddy, fellow crew member or some person to whom the patient was closely attached or identified. The soldier berates himself and considers he is responsible for the death of his friend either directly or indirectly. The mere fact of leaving the group, overseas in combat and returning home to benefit from life in the United States with all its advantages and luxuries is sufficient to produce depression in almost every soldier but it normally subsides in a few weeks. In every case the underlying emotion that has been unrecognized is a negative feeling toward the object toward whom the patient feels guilty.

Psychotic-like States—The psychotic states are temporary and benign and not frequent in returnees since recovery is usually effected by the time they reach the United States. Frequently there is a severe ego breakdown in ability to differentiate and discriminate safe from dangerous reality. Often the person cannot discriminate between the safe reality of here and now, thinking that he is back in combat and reacts accordingly with apprehension and startle or violent aggression. This is particularly true when he closes his eyes or during the transition periods between waking and sleeping.

Progressive Nature of These States—It is apparent that all these states never clearly defined as separate syndromes, are regressive in nature. In some the ego itself has regressed and the resultant personality resembles that of a small child. In others the psychological trends arising from dynamic forces within the depths of the individual overcome the ego's efforts to maintain a mature attitude and produce partial patterns of childish behavior.

The immediate source of the regression is the external weight of severe traumatic situations which the soldier experiences overseas in combat. The degree of preparedness for regression and the pattern adopted has been laid down by the previous personality structure of the individual. Acting on this personality, the severe blows of psychological and physical trauma are temporarily buffeted by the strength which the ego borrows from the group. Once the individual crystallizes out of the group, he becomes dependent on the strength of his own ego and the stability of his ego ideals. These are badly weakened by his initial abandonment of them when he enters the group followed by the catastrophic effects of battle. The external forces of a hostile dangerous world leave no recourse for gratification except phantasy. The ego returns to the only safe and secure position that it has known, its childhood past. In that state it is maintained in dream or phantasy of the past or hope and longing for the future, even enduring further trauma for the ethereal promise of a magical and unrealistic reconstructed future life—a fairy land of dreams unfortunately never to come true.

The soldier then returns home and finds that living out his regressed desires is sadly frustrated. He is a man and a hero and cannot climb on mother's lap, nor can he ever find in reality the complete satisfaction of even partial wishes. Civilians extol him as a great man and the Army insists that he continue his responsibilities in base duties within the United States where restrictions are greater than on overseas duty. Frustrated, his personality is then in conflict with reality. Or an intrapsychic conflict develops between a part of his personality that wishes to deny the regression and the part that wishes to be gratified. The result is anxiety and all the symptoms of a neurosis identical to that which occurs overseas.

Treatment—The treatment is, of course, psychotherapy of a type that first uncovers the essential problems. Persuasion, forcing and exhortation are palliative and largely unsuccessful except to cover up the basic problems. Rational psychotherapy consists in uncovering the conflict whether it be between the patient's ego and reality or an intrapsychic struggle. With plenty of time this can be done by psychiatric interviews. The pressure of great numbers requires shorter methods, hence pentothal is advantageous. In a state of partial narcosis the patient is able to abreact his hidden emotions and synthesize them within his conscious ego, hence we call the

method *narcosynthesis*. After the heavy unconscious loads are released the patient knows what powerful drives he has to deal with and with what uneconomical methods his ego has attempted the task. Supported by the therapist and identified with his strength, the patient can tackle the problem of reeducation. Each type of case presents a different therapeutic problem and the most that we can accomplish in a short time is to relieve the disturbances that have developed as the result of combat or start the patient on his road to recovery. When we encounter a severe psychoneurosis or personality disturbance that has antedated combat and been made worse by it, we can often help the patient understand his previous patterns but seldom effect any profound change.

A comprehensive program of planned recreation, physical activity of the competitive type, and nonconcentrative types of vocational and avocational teaching with a definite purpose is a valuable addition as adjunctive therapy.

The results are most gratifying in that 95 per cent of our officer patients and 80 per cent of our enlisted men are returned to full duty. The difference in these figures is based on the fact that officer selection is much more thorough and careful, hence chronic psychoneuroses or lifelong pathologically crippled characters are fewer and officer motivation for continuing duty and for recovery is higher.

POSTDISCHARGE PROBLEMS

We are not concerned with erasing the effects of combat only to salvage manpower for the war effort. We are also concerned with attempting to send men back to civilian life as independent as possible and as free from regressed trends as can be accomplished. Giving a man a medical discharge invites him to descend the toboggan of dependency, since perpetual veterans' medical care and pensions are his for the asking.

The problem posed by large numbers of soldiers who will return to civilian life on demobilization with tendencies toward regression and susceptibility to react neurotically to rather mild, new traumatic situations is one that will have to be met by all physicians. Every doctor will need to bear in mind the psychological background of the veteran who develops psychosomatic disturbances and other more obviously psychiatric disorders and must be aware of how combat experiences have prepared these men for medical and personality disturbances. The prognosis for good recovery should be as high in civilian life as in the Army, provided that rational and adequate methods of therapy are utilized. There are not enough psychiatrists to carry the load successfully and probably never will be. Thousands of physicians will have to learn the technic of brief psychotherapy and of group psychotherapy. That this is possible has been shown by our success in training general medical officers as assistant psychiatrists.

They have been able to function admirably and, frankly, better than many psychiatrists who are bound up with only diagnostic outlooks. New clinics will have to be opened all over the country. Social workers and clinical psychologists will be required as therapeutic assistants. Social technique will have to be employed based on knowledge of the individual psychological trends but streamlined to mass needs in order to reincorporate these individuals into democratic civilian groups.

The task is tremendous but it must not fail because the consequences would be a profound disturbance of our social structure, since regressed personalities are followers, equally susceptible to leadership by demagogues, psychopathic characters and destructive personalities. Postwar problems of the demobilized combat veteran require cooperative endeavor of all those concerned with human beings, but occupying the most important position with the chance to do the greatest good at the earliest time is the general practitioner, the family doctor.

PSYCHOSOMATIC ASPECTS OF REHABILITATION

MAJOR ALBERT A. ROSNER

MEDICAL CORPS, ARMY OF THE UNITED STATES

THE effective handling of the returned veteran soldier will demand much of this country's skill and ingenuity. A nation utterly unprepared for war, yet capable upon attack of miraculous conversion and successful counterattack, is capable in no less a measure of devoting its whole resources to the reconversion of its tempered soldiers to temperate civilians. One need not underestimate the immensity of the problem. Our armies are large and have wandered deep and far in the mires of war. The war has been grim, and mutilation is no less a prerogative of the mind than it is of the body. Wounded or not, the soldier returning is something other than the soldier having gone.

The soldier wounded poses special problems that are not, in the usually accepted sense, altogether medical or surgical. It is apparent, for example, that a soldier-patient, emancipated by army service from real economic want, and looking forward with trepidation to a return to the competitive economic game, regards somewhat dubiously the healing of his wounds. Anxiety compromises body function and conditions attitude. This attitude may be subject to influences well beyond the reach but not the understanding of his medical administrators. It is apparent that this soldier requires more than skillful attention to his immediate health problem in preparation for his future. The premature discharge of such a soldier, without resolution of his personal conflicts, might prove a costly error, not only for him but for his community. This man's mental attitude as he steps off the train at his home station is a matter of deep and immediate concern to his parents, fiancée, pastor, employer, neighbor and constabulary.

The physician who blinds himself to these social qualities and obligations overlooks matters of deep medical significance. It is his responsibility to view and treat his patient not only as a disabled soldier but as a man with conflict situations that might require attention. He must recognize that there are forces at work which, if poorly channeled, might spell lifelong dependency of an anxiety-ridden postwar casualty upon the government pension list. The physician must recognize the anxiety problem, however disguised, when first it appears on the stage. He must understand why soldiers, who have lived long and intimately with fear, find themselves burdened with its poor relation, anxiety. He must understand that forces which mitigate toward good or bad vegetative function are of direct consequence in the prognosis of any given patient. Knowing these things, the physician is in a position to lend a firm and tactful hand in the early resolution of this kind

of problem which otherwise, in time, shows a disconcerting tendency to dominate the medical situation. He is obliged in other words, to appreciate the soldier problem as a whole, for all that the soldier was, is and hopes to be are matters inextricably bound with his patient's progress.

The reduction of the personality equation to terms of the immediate medical situation should be the first requisite of any therapeutic program. This is not easily done, though some striking advances have been made along these lines.^{12 13 31 46} It has been shown, for example, that certain personality patterns and disease susceptibility are physiologically bound and that dynamic influences imposed by environmental and emotional tensions are prepotent as symptom-producers through vegetative-nervous or hormonal influences, and that treatment aimed at the resolution of anxiety may successfully mediate in chronic illness otherwise considered hopeless. These are no mean accomplishments and bear directly upon the problem of rehabilitation.

The way has been opened by these demonstrations for more complete understanding of illness as a three dimensional problem of very wide scope wherein psychodynamic and physiological elements coexist as prime movers in the course and quality of illness. The therapeutic barriers encountered in war disease and war injury²⁰ emphasize the need for this kind of thinking. Resistance to treatment and chronicity are indigenous to military medicine where the battle of instincts looms stark naked and unadorned and where the element of secondary gain through illness not infrequently displays itself in peculiarly brazen style. The high incidence of so-called psychosomatic illness in the presence of readily apparent and well-defined conflict situations^{11 22, 24 25 32, 35 38 40 45} reiterates the old argument raised by Socrates who, upon returning from the Thracian campaign, insisted that Greek medicine had much to learn from the enemy of psychological insight in disease.

INCIDENCE OF PSYCHOSOMATIC DISORDER

Present-day standards of medical reporting do not permit satisfactory estimation of incidence of so-called psychosomatic illness. The logical method of making such a determination demands cooperative project-studies by representative internists, surgeons, psychiatrists, and other specialists. Combined studies of this type are rare. Exhaustive studies by Dunbar¹⁸ indicate that 80 per cent of routine civilian hospital cases are burdened with psychological problems that bear directly upon the course and progress of their illness. Seventy-five per cent of the difficulties of convalescence, according to Strecker, have their primary origin not in the body but in the mind of the patient.⁴²

The prevalence of disease in the armed service influenced by emotional factors may be judged by the incidence of "neurocirculatory asthenia" in the last world war¹⁴ and the occurrence of gastrointestinal

disease reported by so many sources in this war^{15, 16, 17, 18, 44} Seventy thousand soldiers in the British Army were observed for cardiac disease between 1914-18, only one sixth of this group were shown to have undisputed focal disease of the heart, of the remainder, classified as having the "effort syndrome," 44,000 were pensioned Today, for reasons unknown, the gastrointestinal tract has replaced the heart as an invalid-producer Described as the largest single type of disease among the military sick, gastrointestinal illness was responsible for many hospital admissions in the British Army⁴⁴ The history of neurocirculatory asthenia since DaCosta's time and especially during the two decades following the first world war, substantiates without much question the major role of the psychogenic element in the causation of the syndrome From these studies, neurocirculatory asthenia emerges primarily as a psychological disorder in many of the cases,¹⁴ leaving a good deal of doubt as to whether the term is warranted at all as an alternative for psychoneurosis

The extent to which known medical conditions other than neurocirculatory asthenia may emerge as expressions of psychological conflict and as sensations of inward excitement is problematical A point of practical importance, however, is the fact that military hospital populations show a high incidence of disturbed vegetative function as shown, for example, by the prevalence of syncopal phenomena and nonfocal gastrointestinal or cardiovascular conditions Studies of palmar sweating⁴⁰ in these patients confirms the readily demonstrated fact that the anxiety factor as a least common denominator is largely responsible for symptoms which not infrequently masquerade as organ-connected disease If the study of the mind-body relationship has succeeded in providing insight as to how this transformation is accomplished, psychosomatology will have contributed greatly to the problems of convalescence and rehabilitation

PSYCHOSOMATIC PRINCIPLES

The investigation of the dynamic influence of the nervous system upon end organs and the antidromic effects of somatic disease upon the personality is not new, and in the course of time has reached a fairly high level of evolutionary development The anatomical and physiological foundations of psychosomatology are substantial, and experimental efforts in the clinic and in the laboratory, especially in the field of conditioned reflex, vindicate its claim as a sound and orderly methodology The basic premise that intrapersonal tensions may be translated into symptoms readily appreciated by the patient and recognizable as true physiological events by the physician is supported by evidence from many sources

As one observes a psychotic patient succumb to the hypoglycemic effects of insulin treatment a regular succession of neurological events is unfolded each stage of deepening coma featuring more and more primitive types of reflex behavior. The susceptibility of cortical cells, especially those of recent phylogenetic origin, to anoxic influences is well demonstrated by this interesting experiment in nature, an experiment which recapitulates some prime neurological principles laid down long ago by Hughlings, Jackson, Wilson, Henry Head, Sherrington and others. The process of gradual and progressive dissolution of cortical function effected by insulin induced anoxemia is reciprocated by the appearance of reflex mechanisms ordinarily maintained in tonic inhibitory balance by upper segmental cortical influences. Descending levels of consciousness are accompanied by a descending physiological gradient that roughly recapitulates, in reverse, the development of the human brain.

During early stages of insulin shock, delirious manifestations predominate, characterized by affective lability, uninhibited behavior, archaic speech formulae, motor excitement and recession from reality. As the regression process continues and telencephalic influences recede further and further into the background other cortical release phenomena appear in the form of choreiform and athetoid fragments, representing the phylogenetically older striatal motor system. Sucking movements of the lips, facial grimacing, rigidity and tremor are common. Eventually, if the process is permitted to continue, a condition analogous to decerebrate rigidity supervenes wherein very primitive labyrinthian and neck reflexes, ordinarily deeply buried, are uncovered. The patient in this stage manifests evidences of great disorganization of vegetative function—cardiac abnormalities, hyperhidrosis, respiratory irregularities and poikilothermia are prominent. With the administration of glucose, the physiological trend of events is reversed in greater or lesser detail, and coma emerges into gradually increasing awareness. Full recovery of intellectual grasp and capacity is last to appear frequently long after a relative state of consciousness has obtained.

What does one learn from observing this sequence of physiological events? First, the Sherringtonian principle of segmental domination of the central nervous system—i.e., the successive layer-by-layer domination of lower by higher motor centers—is well illustrated. Second, the whole complicated process of neurophysiological regression is shown to be completely reversible. One gathers moreover that the diencephalon, and in particular the head nuclei of the autonomic nervous system in the hypothalamus, like other elements of the central nervous system, are influenced by controlling mechanisms higher in the neurogenetic segmental scale.

This dissociation principle is also observed in the function of the hypothalamus. Cell groups in the anterior part of the hypothalamus and in the region of the tuber cinereum are considered the head nuclei of the parasympathetic system, whereas other nuclear elements in the posterior parts of the hypothalamus are generally considered the chief centers of sympathetic function. These and other nuclei of the lower part of the diencephalon are intimately bound with controlling mechanism governing the basic vital functions of life—metabolism, temperature, sleep, water balance, gastric motility, ovulation, genital function. Primitive reactions of defense or attack are mediated here and are expressed largely through the autonomic nervous system as visceral or somatic change. Emotional states, such as rage reactions with concomitant peripheral effects, are noted when influence of higher cortical centers is removed by decortication or more spe-

cifically, when fibers passing from the posterior sympathetic nuclei to the cortex are severed^{2, 3, 20} Like other elements of the central nervous segmental hierarchy, sympathetic and parasympathetic affects are magnified when restraining influences of higher centers are removed^{3, 4} The significance of such dissociated function from the point of view of human emotions and its visceral and somatic counterparts cannot be overestimated This is especially true of anxiety syndromes in which distorted and exaggerated fear reactions interfering with normal, purposeful activity operate as dissociated physiological fragments

THE NEUROPHYSIOLOGY OF EMOTIONS

Emotion has been defined as "a highly integrated conative, cognitive and affective-somatic reaction in which not only the central nervous system but the entire organism functions as a psychobiologic whole"²⁸ Emotions are thus conceived as polyphasic composites blending autonomic, cortical and hormonal effects The structural identity of emotions is indicated by the fact that they appear to follow the general laws of segmental integration—they are cortically inhibited, they are activated and exaggerated by cortical release Their physiological specificity is further adducted from the fact that they may be propagated *de novo* in the human by mechanical stimulation during operative exposure through the third ventricle Such stimulation may give rise to crude exaggerated emotional effects of great dramatic intensity²¹ Interestingly enough, feeling tones of more subtle character with greater psychic values, as described by Henry Head, may be further focalized like any other neurological symptom, by referral either to the right or to the left side of the body in accordance with the position of the responsible thalamic lesion

Heavily charged emotional states of great psychiatric complexity may prevail when physiological dissociation between supra- and infra-segmental structures occur During epileptic crises^{6, 7} or the oculogyric crises of epidemic encephalitis^{33, 34} obsessive-compulsive behavior, varieties of forced thinking, delusional patterns, and even projection-mechanisms make their appearance as highly integrated mental symptoms functionally bound to primitive emotional states of subcortical origin At the time they are observed, these dissociated states may approximate classical neurotic or psychotic syndromes They represent dissociated physiological entities capable of reactivation as unit structures and have been termed *unit reaction states*³⁴ The psychopathological configurations that are reactivated *en bloc* during spells are dissociated unit structures delineating specific elements of ideation, emotion, and motility

The identification of emotional elements of this type, possessing definite psychomotor and physiological identity, and capable of forcefully influencing the over-all reactivity of the individual, facilitates the understanding of unconscious mechanisms and their relationship to human behavior The preservation in the brain, intact, beyond the

of consciousness, of unit reaction states or complexes, capable

of catastrophic reactivation as physiologically effective units, agrees entirely with psychiatric conceptions of repression and emotional release. Epileptic or oculogyric crises are not the only trigger mechanisms effecting such release. Psychoanalysis demonstrates this principle routinely. Suggestion by hypnosis may not only implant an unconscious symptom-producing complex, but may accomplish its catharsis with complete relief of experimentally produced symptoms.^{6 10 10} Of equal interest from the psychosomatic standpoint is the fact that experimentally produced anxiety states so induced are accompanied by a full complement of physiological effects translated into cardiovascular and vasomotor symptoms, these, too, disappear with the resolution of the underlying tension state.¹⁰

Following the general principle of dissociated function, emotions like fear, anger or anxiety may be experienced with greater or lesser emphasis on peripheral autonomic gear. Conspicuous somatic effects may dominate the scene.

Sheehan, for example, reports a patient with Raynaud's disease who when aroused to a state of anxiety by the appearance of her physician, repeatedly displayed vasospastic effects.²⁰ One patient, studied at the Neurological Institute, suffered attacks of this sort as a consistent preliminary to submerging her hands in cold water. Subjectively experienced anxiety or fear reactions, on the other hand may find their origin in the soma. Kasanin's patient, capable of enacting her anxiety state with an odd feeling of affectless detachment, was discovered to have a medullary adrenal tumor which when removed resulted in the complete cessation of symptoms.²¹ Injections of adrenalin alone in susceptible individuals may give rise to acute anxiety reactions.

Whether tachycardia, hyperpnea or anxiety dominates, in any given case is a physiological accident that has little bearing on the fundamental fact that emotional states are multidimensional mechanisms that involve both central and peripheral mediators and end organs—the affect system, chemically and anatomically bound, is wholly reciprocal in function.

Anxiety equivalents, expressed in the somatic language of the body as pathological alterations in tonus, secretion and circulation may camouflage the upper segmental sources of the disturbance. *In this sense they may be regarded as autonomic varieties of false-localizing neurological signs.* There is a profusion of evidence that identifies the hypothalamus rather than the stomach as the original focus of peptic ulcer.^{8, 9 20 41} Affect-loaded psychic influences, especially those heavily invested with aggression and hostility bear down upon the autonomic head nuclei of the hypothalamus prevailing upon the final common thoracolumbar autonomic path to effect focal changes in the stomach mucosa as well as generalized adrenergic effects elsewhere in the somatic system. Cholinergic reaction-syndromes on the other hand, follow successful domination by suprasegmental impulses of the craniosacral parasympathetic apparatus.

This method of translating disturbed physiological relationships at high levels into altered function at lower levels, whatever the mode of transmission, permits the designation of psychosomatic symptoms as projected emotional effects. Any factor that compromises the tonic inhibitory influence of the cortex upon the lower centers permits the emergence of physiological reflexes or complexes of a lower phylogenetic order. Regression to more primitive reaction-patterns and potentiation, characteristic of release phenomena, explains the unreasonable intensity of fear, anger or anxiety displayed by the decorticate animal, the hypoglycemic human, the anoxic aviator,¹ the "shell shocked" soldier, the unit reaction state, and the overinhibited, overconditioned animal or human. Whatever disagreement obtains as to the cause of dissociated function as it applies to the human, there is ample evidence that dissociation responses of this order may be reversible and capable of resolution upon reestablishment, by whatever means, of normal intersegmental relationships. The prognosis in any given case, irrespective of the adapted pattern, depends upon the degree of susceptibility to dissociation, it is this susceptibility that measures the psychosomatic distinctions between one personality type and another.

THE PERSONALITY PATTERNS

It is not by accident that the conglomeration that spells schizoid personality also designates its biological fault. If one may predicate on the basis of the evidence that schizophrenia is a disease characterized by dissociation of function, then one is justified in assuming that individuals predisposed to schizophrenia are predisposed to its morbid physiology. The disposition of certain personality types to develop characteristic reaction-patterns has a practical bearing on questions of diagnosis and prognosis and has brought about the formulation of descriptive personality panels. For the most part, however, these labels designate the effect, i.e., *introverted* or *extroverted* personality, rather than the cause. One gains insufficient insight as to the basic nature of the presenting symptoms upon discovering that this patient possesses *hysteroid* or that patient *cycloid* personality features. The common ground for an acceptable system of personality identification must satisfy specific requirements demanded by our knowledge of physiology. It is the susceptibility to dissociated affects and the common affectivity of such dissociation that forms the meeting ground for all grades of psychobiological conflict. Panels formulated in accordance with such principles indicate a prevailing correspondence between somatic syndrome and personality profile.^{13, 46} Elaborate statistical and medicopsychiatric studies have already pointed the way to better psychophysiological understanding in all branches of surgical and medical practice.

THE LATER FATE OF ANXIETY

Rehabilitation demands a three-dimensional approach to medical and surgical problems that takes due account of conflictual and emotional elements of the personality situation. War breeds psychological regression. The normal inhibitory forces exerted by the cortex in the presence of long-continued exposure to the fear and anxiety of the war situation become attenuated, especially in the presence of chronic fatigue, and symptoms of the regressive type appear. The adaptation of more primitive reflexological modes of behavior, with its dulling of the discriminative capacity, may serve a useful purpose as a defense against anxiety.³⁰ Carried further, however, the regression process uncovers reaction-patterns inimicable to the health and the safety of either the soldier or his organization and the soldier becomes a neuro-psychiatric casualty.

This process of psychological reversal accounts for the hyperexcitability, lack of emotional control, inability to select and discriminate between stimuli, and the state of total reactivity to innocuous stimuli that forms the core of soldier neuroses.^{25 41} Exaggerated vegetative effects are reflected in the gastrointestinal, cardiovascular and respiratory systems as diarrhea, anorexia, hyperemesis, palpitation, tachypnea and the like, sympatheticotonic effects predominating. Anxiety engendered during prolonged exposure to the chaos or monotony of military life may emerge, like certain viruses, only when circumstances are propitious. The persistence of anxiety and its bound autonomic elements, long after precipitating circumstances are gone, poses real therapeutic obstacles.^{35 36} Any program aimed at complete restitution of the health of the soldier must anticipate a high incidence of anxiety and the propensity of anxiety elements to invest illness, especially chronic illness, with supernatant properties purely psychogenic. In its broader aspects the later fate of war-engendered anxiety is an economic as well as a medical issue.

PRINCIPLES OF TREATMENT

Lowered threshold to fear is matched by lowered threshold to suggestion. Neglect of this potentially dangerous susceptibility may enormously complicate the healing program. One can only speculate on how many invalids have been made, not on the battlefield but in the safe environs of the hospital, by overattention to somatic ailments whose tenacity, if not origin, stems from anxiety sources. Overzealous treatment of the organ at the expense of the personality may in part have contributed to the rising incidence of psychosomatic problems.²³ Even the presence of serious somatic illness is no contraindication to judicious avoidance of overconcern on the part of the physician. He must decline the bait of latent anxiety and its promise to the patient of secondary gain.

The prevailing state of psychological disequilibrium that marks

the convalescent soldier demands a reevaluation of some basic principles of medical therapy. Symptomatic treatment can be dangerously provocative. The abuse of bed rest⁴³ in a cardiac patient, for example, may reverse the process of recovery and reduce exercise tolerance to zero. Aside from deleterious psychological effects, ill-considered rest, in the orthopedic patient, may be responsible for bone atrophy, muscle wasting or embolism. In any patient subject to the restraining influence of the bed, constipation, cathartic habituation, and vasomotor atonia are rest-induced sequelae that, as anxiety producers, are better anticipated and avoided than regretted in retrospect.

The use of narcotics, like rest, must be reevaluated in the rehabilitation process. Though the selective intravenous use of barbiturate derivatives has a proven value, prolonged dependence upon sedatives may challenge recovery. The sedative habit is only one manifestation of treatment resistance unconsciously adapted by the convalescent patient. Less likely to become tools of latent neurotic tendencies are the belladonna derivatives, benzedrine and ergotamine, effective in the treatment of combat-induced neurovegetative disorders²⁴ that tend to persist long after other elements of the medical situation are gone. Pharmacodynamic effects, however, will never resolve psychologically determined symptoms. This is a psychiatric responsibility to be shared by all members of the medical faculty.

The neuropsychiatrist cannot dissociate himself from problems of convalescence, that psychosomatic complex—the healing human body—invites active neuropsychiatric attention³⁶ and affords the neuropsychiatrist an opportunity to provide a fuller measure of appreciation of the psychodynamics and true personality behind the symptom. His experience may be of assistance in the formation and execution of interesting, progressive, day-by-day convalescent schedules for patients. Occupational therapy, like any other form of therapy, must be exactly and scientifically prescribed. The rehabilitation of the soldier, irrespective of diagnosis, should begin at the earliest possible moment, should be modified according to his progress, and should either be completed or well under way before he is passed on from the hospital to succeeding agencies. The deployment of mental hygiene units in transition and supervisory roles³⁷ will anticipate the uncertainty and indecision incident to hospital discharge and facilitate the substitution of the civilian for the military way of life.

A normal balance between thinking and feeling is seriously jeopardized by war experience. Primordial fear, unbound, after centuries of painstaking repression, destroys this equilibrium. The reconquest of fear and its equivalents is the common task of the moment, it is here that psychosomatic understanding provides its full and special share of hope and promise.

RECONDITIONING OF TRANSITORILY MALADJUSTED SOLDIERS

COLONEL THOMAS G. TOUSEY
MEDICAL CORPS, UNITED STATES ARMY

This article deals only with those soldiers who have had to be removed from task force units at a staging camp, while en route overseas, for a mental condition ordinarily recognized as psychoneurosis. A careful study of a large number of these cases leads to the conclusion that they mostly were soldiers temporarily out of harmony with their environments rather than afflicted with a true mental disorder of psychogenic origin. In other words, it was felt that they were maladjusted rather than psychoneurotic. Their symptoms on admission uniformly were severe enough to warrant their being removed from task force units but, because many of them were revealing symptoms for the first time, it was felt that these symptoms were temporary and were precipitated because of apprehension arising from thoughts of impending embarkation. It must be remembered that all of this personnel had been through months or years of training and maneuvers and should have been inured to all war conditions short of actual combat. It also must be kept in mind that because of the training they had undergone they were especially valuable to the Army and the war effort and their prompt reconditioning was most important. It was for these reasons that the 'maladjusted regimen,' as it was called, was established at a camp in March, 1943.

PROBLEMS PRESENTED BY MALADJUSTED PERSONNEL

There were several possible approaches to the problems presented by this personnel. These men could have been subjected to a program similar to patient reconditioning programs now conducted in all Army hospitals, or they could have been transferred to special training battalions under command of line officers, or they could have been labeled psychoneurotic and considered to have lost all usefulness to the Army and have been discharged.

Early in 1943 it was realized that the number of soldiers being discharged from the Army with the diagnosis of psychoneurosis was very great. Newspaper and popular magazine articles on psychoneurosis were becoming more frequent and it was not uncommon to hear civilians jokingly remark about psychoneurotics getting out of the Army. Thoughtful civilians were taking a more serious view of the matter and were showing their concern for the Army because of the large numbers being let out with the diagnosis of psychoneurosis for the individuals themselves who, with the stigma of the diagnosis, were

finding it difficult to get employment, and because of the implication that the younger generation did not have the mental stamina commonly ascribed to youthful Americans. Because of these observations, follow-up letters were sent to the next of kin of all who had been discharged from the Army at this camp for psychoneurosis, and from the replies it was evident that the great majority had adjusted themselves to their civilian environment almost immediately after separation from the service. The questionnaires clearly indicated that freedom from military restraint, loss of cause for apprehension, and cessation of letters and messages from home that caused emotional storms, coupled with the privileges of continuous liberty and comforts of an agreeable environment, were the dominating reasons.

The composite psychoneurotic, therefore, as seen at this camp, is one without the mental stamina to undergo severe or unusual strain. He came into the Army that way and his mental conditioning was not completed during his training. This is partly because a line commander cannot evaluate evidences of lack of mental stability with the same ease that he can a lowered physical state. This fact emphasizes the need for a short, practical course for company officers in methods of detecting mental upsets.

To develop a system or plan for reconditioning these individuals to the degree that they once again would be useful members of the military establishment, it was necessary first to understand fully the composite psychoneurotic and how to determine his peculiarities. First of all, he is a tense individual with a stormy mind surrounded with a shell of resistance to outside influences from which he cannot escape without help. That bizarre definition forms the basis of the plan of treatment used successfully for one and a half years.

CAUSES AND SIGNS OF MALADJUSTMENT

Why should an individual withdraw into a shell? Just as a person quickly withdraws his hand when he touches something hot, so a soldier withdraws mentally from something that irritates his sensorium. He is irritated by restraints, the "musts" of army life. Varying and ever-increasing degrees of apprehension cause a subconscious withdrawal and soon he develops a resistance to circumstances that ordinarily would cause him no concern. To further aggravate the condition, he writes of his unpleasant situation to members of his family who with normal sympathy reply with letters that create emotional storms. The officer who commands the soldier inflicts punishments for derelictions, causing resentment and an inferiority complex, and the build-up for the diagnosis of psychoneurosis is complete.

From the clinical side, the maladjusted soldier presents certain general complaints, the most common of which are as follows: general weakness, 60 per cent, depression, headaches, general body pains, each 50 per cent, insomnia, 30 per cent, and loss of appetite, 26 per cent.

In the early stages of his training a soldier is credulous and tractable, and an incipient condition could and should be recognized. He should be helped then by proper orientation and suggestion. By the time he reaches a port of embarkation staging camp and is ready to sail to a theater of operations his shell has become so dense that treatment away from his unit is necessary. Each such case represents a loss of manpower in an Army that desperately needs every fighting man. More emphasis must be placed on early mental conditioning which would obviate the need for much reconditioning. During training periods it should be required that unit medical officers constantly accompany troops on every training exercise into the field and devote much of their time to making observations of personnel. Too much time is spent in dispensaries in base camps waiting for things to happen. Every time a soldier falls out of a formation or lags on marches, there is a physical or mental reason and he should be studied on the spot by the accompanying medical officer.

PRINCIPLES OF MANAGEMENT

The principles involved in the management of maladjusted personnel at a staging area included

- 1 The avoidance of the diagnosis of psychoneurosis until such time as it is fully determined that the soldier cannot be restored to useful military service and must be discharged. It was found that a soldier, if told that he is a psychoneurotic, will quickly add depression to the rest of his symptoms and will be that much harder to approach. It has been noted also that in their efforts to get themselves discharged from the service they feel that if they have psychoneurosis they are entitled to immediate separation and any attempts at reconditioning are resented and therefore impeded.

- 2 The second principle is to return all such personnel to full duty status as soon as their symptoms are recognized—approximately one week after admission—so that they may be assigned work of a useful nature. This is important, for these individuals become impatient with temporizing procedures such as the minor craft work often carried on in hospitals. They are men and in their reconditioning we must remember that we are dealing with men's minds.

- 3 Rest, in its true sense, also is important. It must be remembered however, that "absence of occupation is not rest, a mind quite vacant is a mind distressed." Healthful discussions and orientation talks serve to supply thoughts that will afford mental rest.

- 4 Again it is necessary to make a soldier realize the importance to himself of his own reconditioning. He must be inspired to readjust himself and to understand that in so doing he will gain self-confidence necessary to his complete restoration.

- 5 Dispersion of maladjusted individuals, as they are known in this program among normal troops is essential. It was discovered early that

when housed together, even on a duty status, some felt that the finger of mockery was pointed at them. They, therefore, are scattered among other troops for duty, rations and quarters. In fact, other troops are not cognizant that maladjusted soldiers are other than newly assigned or attached personnel. This dispersion also precludes several from getting together to discuss their symptoms. There is one in every such group who will dominate all and may exercise a bad influence.

6 It is important to make all in the group feel that they are normal soldiers living, working, playing and conducting themselves as would normal soldiers. This association with normal soldiers has served to stimulate, through pride, a desire to correct their own weaknesses. It also prevents unwarranted solicitous attention from others.

7 Lastly, duties assigned these individuals initially must be within their capabilities and of such a nature that quickly attained results in which they can take pride are certain. Nonfulfillment of purpose causes a bad reaction in the early processes of reconditioning. All soldiers are encouraged to work well, to think for themselves, and to absorb responsibilities incident to the task at hand.

MEANS OF GAINING THE INITIAL CONTACT

But before any of these principles can be applied it is necessary to penetrate the shells of resistance built up about their conscious selves. This initial entry into a mentally disturbed man's inner self is the most difficult part of the problem of his reconditioning and the most important part. Once such an entry has been made, it is found the soldier has developed sufficient confidence in those helping him so that he becomes amenable to progressive suggestions. This phase of treatment must be started while the soldier is still on a patient status.

It has been found that there are many ways of gaining this initial contact. Arousing his interest in something new to him has been the most successful. A skilled soldier artist develops the first contact with some by teaching soldier patients some of the basic principles of sketching and incidentally has them draw pictures. They are surprised at their ability and their interest is aroused. Some of the more difficult patients have been started through this means. Clay modeling has proved equally effective, partly because it is a creative art and its results are quickly apparent and usually are highly satisfactory. Those conducting such classes must not only be artists, they must be psychologists and sincerely interested in the therapy they are carrying out. Gardening in season stands high as a method of gaining access to a patient's confidence and, in addition, access gained through this means leads to more rapid progress of the patient toward recovery. Gardening affords fresh air and sunshine, general body exercise of varying degrees, stimulation of the mind by the mere process of watching things grow, the sense of useful production, and the satisfaction of personal gain by eating the fruits and vegetables. But those

items do not constitute the only benefits derived from gardening therapy. As a man works in the garden he "rests," his tension eases, his "guards are down" so to speak, and he is less resistant to helpful indoctrination. Those conducting this training are well versed in amateur gardening and, more important, they have a thorough knowledge of this purpose of the reconditioning program. Members of garden clubs are particularly valuable for this work, especially when the amateur gardener also is a trained nurse with deep, sympathetic and practical understanding.

There are a variety of ways and means available to gain contact with these patients, to pierce their shells. Other facilities available at this camp include a carpenter shop, furniture repair shop and printing shop. It will again be noted that only facilities in which practical and masculine work is done are utilized. The carpenter shop is used only for repair work of a general camp utility nature such as repairing screens, rehanging doors, making shelves and other "gadgets" needed about the hospital. Many patients of their own volition have devised useful articles for the wards and made them in the shop. The furniture repair section rebuilds broken or damaged furniture not only for the hospital but for the entire camp. Overstuffed chairs and sofas are torn down to the bare frame and brought back to full usefulness again. In the print shop type is set for letterheads and other forms and the printing accomplished. A small weekly hospital paper also is printed here.

In these various facilities it is nearly always found that one of the work projects will arouse a sufficient demonstration of interest to permit a patient to go on to duty therapy. Sometimes a judicious shifting of a patient from one facility to another is required to gain the desired early reaction, but shifting is carried out with caution as patients often resist or resent reconditioning processes initially and invite changes of work during the initial stages to delay the procedure.

FULL DUTY PERIOD OF RECONDITIONING

Following this initial breakthrough the soldier is quickly discharged from the hospital to a full duty status. Some patients are, in fact, ready for full duty with training units at this time. Most, however, are found to need medical supervision during the early days of their full duty period, and so, on request of the hospital commander to the post commander, the soldier is attached to the Medical Detachment for duty, rations and quarters. It is most important that the transfer from patient status to the full duty status be made as early as practical to prevent patients from developing a mental condition comparable to the physical condition known as "drug fastness." This reconditioning therapy fastness must be avoided at all costs as it is hard to overcome. Rapid progress must be attained up to the point at which the patient begins to proceed normally about his assigned duties.

In transferring patients from hospital status to full duty, the administrative procedures are simple. A notice is forwarded to the Post Commander stating that the patient will be discharged from the hospital to duty and requesting that he be attached to the Medical Detachment for duty, rations and quarters until such time as he is considered fit for return to his own or some other organization. This procedure, of course, had been approved at the institution of the program. The soldier is discharged by action of the Hospital Disposition Board and goes to the Replacement Pool, to which he was assigned when his unit departed for overseas, assembles his clothing and equipment, and then reports to the Medical Detachment Commander for duty.

The procedure is normal in all ways and so soldiers about the hospital have no knowledge that the new soldier has ever been a patient in the mental wards. He is assigned to a barrack, care being taken that maladjusted trainees are not grouped in any one platoon. To all intents and purposes, all personnel so assigned are simply soldiers attached for duty and there is no stigma connected with them in any way. The Detachment Commander is a carefully selected officer who understands men and who is respected by them under all conditions. He personally interviews all soldiers who are assigned or attached to his unit, including those attached for maladjusted training. After a carefully conducted interview, he assigns each to a definite duty in the medical service, and at one time or another, almost every position in the hospital has been filled by one or more maladjusted soldiers.

Immediately following assignment the soldier comes under the notice of three officers who will observe his actions and reactions, his attention to duty, and all other military qualifications that a good soldier should have while in the service. The observations are made without the soldier's knowledge and without consultation between the officers. Every ten days each officer makes a brief narrative report on each maladjusted soldier to the Hospital Commander, from which is judged the progress being made by each. One of the reporting officers, the Detachment Commander, is not a medical officer so his estimates are based on an appraisal such as any line commander would make and not on professional judgment. He reports on the soldier's neatness and military bearing, his attitude toward other soldiers, particularly non-commissioned officers, in the barracks, at mess, or at work, is he a good mixer or does he stay by himself? If he has any habits not compatible with good military discipline, it is made a matter of record. Is he prompt at formations, does he complain about his status or his environment? What is his attitude toward the Army, the country, the war? This information all must be gained by observation, not questioning, for this soldier is on a duty status and he must not be made, to any degree, to feel he is a patient or that his every action is being watched.

EXAMPLE 1 (Report by Detachment Commanding Officer) " ————— is a conscientious worker, shows some initiative, tries to keep himself busy. He seems to be rather happy in his job. He is neat and courteous and has made no complaints of any physical ailments. He is trying and wants to learn the routine in the dispensary."

Another officer to report regularly on each maladjusted soldier is the officer under whom he works. This officer may or may not be a medical officer and the report is made from a viewpoint other than professional. How does the soldier apply himself to his work? Does he carry out his duties without urging? Is his interest aroused or sustained? Does he cooperate with others? Accuracy, speed, and demeanor are other subjects of this report. Progress made in essential elements since entering the maladjusted group is particularly important as an item of report.

EXAMPLE 2 (Report by officer under whom soldier is working) " ————— is excellent. I would like to have more like him. He has learned to give shots and to handle the sick book. With a little more training he could almost be called a full fledged dispensary man. I doubt if he could ever do heavy work because he gets badly 'winded'. At the moment he is upset because he is classed as maladjusted. He says he is working hard to overcome his nervous upset and he is doing a grand job."

The third officer who regularly reports on the progress of the maladjusted personnel is the psychiatrist. His approach to each individual is that of the doctor recently in charge of the case and who is, therefore, interested in his progress. By informal talks in the corridors, at the place of the soldier's duty, or at times, in the office of the psychiatrist, he determines from his professional viewpoint the mental state of the soldier and whether the soldier is progressively improving. He offers in his report such recommendations as may be indicated.

EXAMPLE 3 (Report by psychiatrist) "This soldier was making a satisfactory adjustment as long as he was in the dispensary. He has recently been assigned to the carpenter shop where the noise affected him badly. He is now more tense and anxious. It is recommended that he be reassigned to dispensary work."

(Note: The limitations on this soldier's readjustment noted over a period of four weeks led to his assignment to the Station Hospital Detachment, where during the past several months he has carried out his duties in a dispensary in a superior manner and he released a general military service soldier for overseas duty.)

From the assembled reports the Hospital Commander judges the status of each individual and directs his future handling. When a soldier makes highly satisfactory progress, his trial in a department where the work is of an entirely different nature is directed. Every effort is made to detect limitations on readjustment and also to determine just how best the readjusted soldier's services can be utilized. All soldiers

are pressed to accept more and more responsibilities in their work. A noncommissioned officer, before final recommendations for his disposition are made, is put in charge of some detail to determine how far he can be trusted to handle other men. Finally one of the following recommendations is sent to his unit commander who, in practically all cases in a staging camp, is the commanding officer of the Replacement Pool.

1 This soldier is returned to full military duty.

2 This soldier is returned to duty with the recommendation that his military service be limited to the United States. He has shown special adaptability as a (cook).

3 This soldier is returned to duty. Because of his tendency to (persistent dizziness) it is recommended that he be assigned to the Station Complement Medical Detachment, or to a similar unit in another camp, where he will be under close supervision of medical officers. He has shown special adaptability as a (clerk).

4 This soldier has not reacted well during his duty in the Maladjusted Regimen, is not considered suitable for retention in the Army, and will be discharged on Certificate of Disability, diagnosis, psychoneurosis.

During the latter stages of their readjustment, this personnel reports to an assembly point one hour each day, where orientation talks are given. One day each week a somewhat detailed account of war activities is given them and they are shown war or training films. On all other days talks are given by business and professional men from the nearby communities who volunteered their services. These are sound, practical and stimulating talks designed to broaden interests. They are excellently received.

SUMMARY AND CONCLUSIONS

To restate briefly, the treatment utilized in the Maladjusted Regimen consists of two phases, i.e., the breakdown of the soldier's resistance to reconditioning through stimulation of interest in one of the shops or in the garden, during a very brief period, and the full duty period with one hour a day orientation. Throughout the training, special care is given to the physical build-up through calisthenic exercise, marches and other activities taken with the Medical Detachment. Special facilities also are furnished so that all can take sun baths daily under the careful control of technicians.

In conclusion, it is desirable to emphasize the simplicity of the program for maladjusted soldiers through work therapy. It strengthens the mental fabric of an individual to the degree that his mental armor is able to resist impacts from whatever source. He gains confidence and pride in himself to the extent that he overcomes obsessions, inhibitions and neurasthenic blocks. He is less credulous. Through his continuous performance of useful military duties and his mingling with highly trained troops he develops new interests in military matters. The pe-

mod of duty therapy also offers the psychiatrist an excellent opportunity to study and evaluate various symptoms and arrive at a sound decision

The early removing of maladjusted personnel from the ward atmosphere is believed to be one of the most important principles of treatment because it immediately frees his mind of a real care. The work performed by the individual incident to his duty assignment is the factor that braces him against recurrences

RECONDITIONING THE MALARIA PATIENT

CAPTAIN WILLIAM L. NOE, JR. AND MAJOR EARL W. PARKS
MEDICAL CORPS, ARMY OF UNITED STATES

ALTHOUGH therapy of the acute attack of malaria with atabrine or quinine is highly effective, no known form of treatment will *prevent chronic relapses* in a certain percentage (perhaps 10 per cent) of all individuals who are infected. Some patients who have been observed have had relapses a dozen times at approximately monthly intervals, and still others have undergone twenty or more relapses. The management of the semi-invalidism associated with this chronic relapsing type of malaria is essentially a military problem at present, but is likely to become an important consideration in civilian medical practice following demobilization of the armed forces.

Inasmuch as relapsing malaria not only lowers the physical stamina of the patient, but also lowers his morale, it is now well recognized that the soldier with this disease requires, in addition to drug therapy, other forms of treatment. In order to accomplish this purpose, a Reconditioning Program has been developed at Hammond General Hospital which has proved highly satisfactory in a number of respects.¹ The program has been divided into two sections. The first includes only the hospitalized patients and is carried out on the wards of the Tropical Disease Section of the Medical Service. The second is carried out at the Advanced Reconditioning Center apart from the hospital where the patients live in army barracks. The reconditioning program in each of these two sections will be discussed separately. The institution of this program was facilitated by the Comprehensive War Department Reconditioning Program under the direction of which all patients in military hospitals, except those who are seriously ill or those in whom any slight exercise might have a deleterious effect, are required to undergo graduated series of exercises.² Depending upon their physical tolerance, the patients are classified into four groups. Briefly, Class IV includes bed patients who receive only slight exercise, perhaps limited to certain muscle groups or to certain parts of the body depending upon the disability that is present. Those in the remaining classes (III, II and I) receive graduated increasing physical activities so that those in Class I are able to perform physically in the manner that is required of a soldier on field duty. In addition, under the provisions of the War Department Reconditioning Program, all patients are encouraged to engage in vocational, diversional and educational activities.

THE RECONDITIONING PROGRAM IN THE HOSPITAL

The hospital reconditioning program is concerned chiefly with adjusting the patient's morale to his relapsing illness, keeping him profitably occupied while he is in the hospital and preparing him physically for the Advanced Reconditioning Section. Only Class IV and III patients are cared for in the hospital, whereas Class II and I patients are observed at the Advanced Reconditioning Center away from the hospital atmosphere. Patients with acute malarial activity are confined to bed and do not participate in the Reconditioning Program. Under the optimum conditions that exist in a military hospital in the Continental United States, the general condition of patients after an acute attack of malarial fever is good so that the scope of their reconditioning activities can be increased quite rapidly following termination of the acute attack. Accordingly, they are started in Class IV as soon as the temperature has been normal for forty-eight hours, but must remain on the screened malarial wards until two successive blood smears taken forty-eight hours apart have been reported negative for parasites.

In order to aid their morale when these patients enter Class IV in the reconditioning program it is essential that the medical officers in charge reassure them that their chronic relapsing disease will eventually be cured without untoward and permanent sequelae. They are then urged to matriculate in any of the United States Armed Force Institute courses that they might choose. Occupational therapy in diverse forms is made available on the wards daily, a definite effort being put forth to guide this therapy in a vocational direction whenever possible. Books representing a wide range of educational and vocational subjects as well as recent "best sellers" are brought to the ward daily from the mobile branch of the Red Cross Library. The patients are encouraged to read on sociologic, economic, military and other problems relative to both the war and to the postwar reconstruction period.

Diversional therapy is also provided by the Red Cross and by other volunteer organizations. This diversional therapy consists partly in the presentation on the wards of sound motion pictures, shows and entertainments by United Service Organization Troupes, and partly in games such as ping-pong, croquet and shuffle board, which are available either on the ward or in the immediate environment (for Class III patients). The patients in Class IV also take part in mild calisthenics either in the ward or in a special screened enclosure adjacent to the ward. It should be pointed out here that this extensive program is made possible only through the close cooperation of the medical service with other agencies in the hospital such as the Red Cross, the reconditioning branch, the orientation and educational officer, the special service officer, and the occupational therapy division. These features of the program are extended throughout the period that the patient is in the advanced reconditioning center and until he is returned to duty.

Within one week of an acute attack, patients have usually recovered sufficiently to be advanced from Class IV to Class III. They are then able to leave the screened malarial wards so that they can attend lectures embracing a variety of timely subjects, which are given either by other hospital patients who have returned from overseas theaters of operations, by the orientation officer or his assistants, or by members of the faculty of nearby colleges. The patients may now also be granted passes which permit them to leave the hospital grounds for short periods. By this time the type of duty that is best suited to the individual patient has been selected by the Reclassification Officer after consideration of the patient's skills, army experience and physical condition.

A special effort is made during this period to recondition the patient to the amount of physical activity which will approach that expected of him when he is returned to duty status. Calisthenics are given out-of-doors, adjacent to the ward, at a regular time each day under the supervision of a physical education instructor. These exercises, together with competitive games such as volley ball, shooting baskets, tossing a baseball or football, are gradually increased in duration and intensity as they are tolerated. If the patient is able to gain weight or to maintain his normal weight, and to possess a general sense of well being, and if he is free of malarial activity for approximately two weeks while indulging in fairly vigorous and prolonged exercise, he is transferred from the hospital to Class II at the Advanced Reconditioning Center for further training.

THE RECONDITIONING PROGRAM AT THE ADVANCED RECONDITIONING CENTER

The chief mission of the Advanced Reconditioning Center, as stated by Brigadier General John M. Willis,³ is to return the soldier to duty in the best possible condition in the shortest possible time. During the course of study of patients with malaria and other conditions at the advanced center of this hospital, a number of observations have been made with regard to best accomplishing this aim. The patient with malaria presents many special problems in reconditioning. One of these is the fact that, in addition to malaria, he may also suffer from a battle wound or have some other disease. Another is that, according to some authorities, exercise may increase the probability of, or induce a recurrence of, an acute attack of malaria. The reconditioning program has afforded an excellent opportunity to study this latter aspect of the problem, inasmuch as these patients, who are designated as trainees, undergo a progressive physical training program, including modified and remedial calisthenics, military drill, sports, hikes and work details.

The basis for this report of the Advanced Center is the observation of sixty-four patients with malaria who were observed during the

three months' period from June to August, 1944. These patients were transferred from the Medical Service after they were considered to have reached maximum hospital improvement, were ambulatory and had taken part in calisthenics of the Class III group. They were physically capable of participating in Class II of the Reconditioning Program. These patients had been evacuated from endemic malarial areas of the Southwest Pacific and North Africa, two to thirteen months previously. In all of these patients the diagnosis of malaria was conclusively established. Eighteen of the group were considered by the Medical Service to have chronic relapsing malaria, since each of them had exhibited five or more recurrences of malaria over an average period of five months.

When they reached the Advanced Reconditioning Center each one of the group of sixty-four patients was classified as a Class II trainee. It was planned to retain these patients in Class II for approximately two weeks, and then to transfer those who appeared to possess the necessary physical stamina to Class I. However, none of them were ever qualified for Class I as this advancement required the patients to demonstrate their fitness by executing satisfactorily a series of specified physical efficiency tests and completing a 15-mile hike. Consequently those who were sent to duty were discharged directly from Class II with certain specified physical limitations.

Analysis of this entire group of sixty-four patients reveals that thirty-seven patients or 57.7 per cent developed a malarial relapse after an average period of 36.7 days at the Advanced Reconditioning Center. Eight patients of the group had two relapses, an average of 31.2 days intervening between the first and second recurrences in each of these. These figures are of particular interest when they are compared with a series of 216 similar patients with malaria observed under hospital conditions over a period of thirteen consecutive weeks before the institution of the reconditioning program. These hospital patients regardless of the type of malarial drug treatment they received showed a relapse rate of 57 per cent with an average of thirty-four days intervening between relapses.

COMMENT

At present, available statistics are not conclusive regarding the probable termination of the course of relapsing *Plasmodium vivax* infection or the establishment of an average period which may elapse between the first recurrence date and final cure in patients evacuated from endemic malarial areas of the Southwest Pacific and North Africa. Studies of data compiled at Hammond General Hospital indicate that longer periods of observation are necessary in order to clarify this perplexing problem, particularly in view of the fact that the relapse rate of malaria patients may vary markedly. More definite information will undoubtedly be available in the near future.

In this series of cases the relapse rate of malaria patients with *P. vivax* type of infection who were observed at the Advanced Reconditioning Section was the same as that of the control series of 216 similar cases managed entirely under restricted hospital conditions. In view of these findings the advantage of placing this type of malaria patient in an Advanced Physical Reconditioning Program might be questioned. However, it is generally recognized that patients who remain in the hospital for prolonged periods of time are apt to become introspective, develop fixation of their symptoms and manifest varying degrees of psychoneurotic symptoms. This is one of the major points which the War Department Reconditioning Program seeks to correct. For this reason and inasmuch as the relapse rate was identical in the two groups, and since there was demonstrated an improvement in mental attitude and desire to return to duty in those patients who underwent physical exercise at the Advanced Reconditioning Center, it is felt that these patients should be transferred to this section as soon as possible rather than undergo continuous observation of a hospital regimen type in a hospital atmosphere.

SUMMARY

1 The problems involved and the methods utilized in carrying out the War Department reconditioning program in patients with chronic relapsing malaria in a military general hospital in the zone of the interior are cited.

2 An attempt has been made to observe the effect of physical exercise upon the relapse rate of recurrent *Plasmodium vivax* malarial fever.

3 Sixty-four patients with chronic recurring malaria were observed in the Advanced Reconditioning Center of a military general hospital for a period of three months. The average relapse rate was 57.7 per cent and the average period between relapses was 36.7 days.

4 A control series of 216 similar patients were observed under hospital conditions over a period of thirteen weeks. The average relapse rate was 57 per cent and the average period between relapses was thirty-four days.

5 From a military standpoint, the care of these patients in an Advanced Reconditioning Center away from the hospital atmosphere appears advisable.

THE CONVALESCENT CARE OF RHEUMATIC FEVER IN THE ARMY AIR FORCES

LT COLONEL IRVING ERSILER

MEDICAL CORPS ARMY OF THE UNITED STATES

THE occurrence in 1942 and 1943 of a large number of cases of acute rheumatic fever among personnel of the Army Air Forces was the stimulus for the development in the spring of 1943 of a Rheumatic Fever Control Program. The details of the overall program have been described elsewhere.¹ Forty of the larger AAF hospitals were selected to cooperate in the program. The posts chosen for study were in areas of high incidence of rheumatic fever, in areas of low incidence, and in intermediate areas. Laboratories have been set up with the equipment and personnel needed for grouping and typing of hemolytic streptococci. Rheumatic fever was made a reportable disease on the weekly statistical report and a central registry of all cases of rheumatic fever is maintained in the Office of the Air Surgeon. As one phase of the rheumatic fever control study, a definitive convalescent program was developed.

Ideal care of patients with rheumatic fever involves adequate medical care during the acute and subacute phases of the disease, provision for long term medical follow-up, hospitalization and nursing care during the acute phase of the illness, prolonged hospitalization and nursing care for the occasional patient with chronic progressive disease, arrangement for protracted bed care in sanatoria, convalescent homes or in the patient's home following discharge from the hospital, medical-social service facilities to make available welfare resources where needed and to assist in follow-up studies, provision for schooling, occupational therapy, and in some cases vocational training, and residence in an area of low incidence of rheumatic fever for a prolonged period of time following recovery to minimize the possibility of recurrence.

The complexity of adequate care and the low economic level of many patients make the proper treatment of rheumatic fever expensive and too time-consuming for the physician. For these reasons it has not been possible to supply adequate care for any large group of rheumatic fever patients in this country. In the AAF Rheumatic Fever Control Program, an attempt has been made to supply as close to ideal care as possible for these patients. The convalescent aspect of the program has three major phases: medical, physical training, and vocational.

From the Army Air Forces Rheumatic Fever Control Program.

MEDICAL PHASE

In general, the usually accepted conservative precepts in regard to the management of rheumatic fever are adhered to. Of particular interest is an attempted standardization of criteria for diagnosis following Jones.² The necessity for uniform criteria has been appreciated by all workers. Variations in some details of management, particularly treatment, occur due to individual medical viewpoints.

The usual case of rheumatic fever is hospitalized at the AAF Station Hospital on the post where the illness occurs or at the nearest AAF Regional Hospital. As soon as the patient can be transported safely he is moved to one of a group of AAF Regional Hospitals designated for the convalescent care of rheumatic fever. The hospitals in this group are all below the 34th parallel in the United States and are in areas of low incidence of rheumatic fever. The latter has been ascertained both by clinical experience and by a comprehensive bacteriological survey of the distribution of Group A hemolytic streptococci and its relationship to the incidence of rheumatic fever.⁸ Rheumatic fever patients are kept at the hospitals designated for convalescent care for a period of six months after the onset of the illness or for any extension of this period necessary for maximal recovery. The only exception to this rule is in the case of those patients who are to be separated from the service because of unusually severe rheumatic fever or its sequelae. These patients are discharged from the Army on the completion of maximum hospital benefits. Personnel are separated from the service because of rheumatic fever if the active phase of the disease has been unduly long, if there is persistent heart failure or cardiac enlargement following the acute phase of the disease, if there has been a previous attack within two years or if there is residual cardiac disease at the end of the period of hospitalization. Exception to the last provision may be made in the case of highly skilled personnel who may be utilized on a restricted activity basis if the residual cardiac disease has static characteristics and is without evidence of significant impairment of cardiac function. To date, approximately 70 per cent of all patients with rheumatic fever are returning to duty.

Upon completion of treatment at the hospitals designated for convalescent care, personnel are assigned for duty for an additional six months' period to AAF Stations in the continental United States in areas of low incidence of rheumatic fever. In general, areas of the United States south of the 34th parallel (below the 36th parallel in California) can be considered to be areas of low incidence of rheumatic fever and are recommended for assignment. Upon termination of six months' duty in such an assignment, these individuals are reexamined and, if found to be free from evidence of rheumatic fever or its sequelae, and otherwise physically qualified, are declared fit for general duty. The only exceptions to this are the skilled personnel with residual cardiac disease noted above. If these individuals are retained

in service they are assigned to duty in an area of low incidence and disqualified for transfer overseas.

Under this plan patients with rheumatic fever are under expert medical observation for a minimal period of six months, following this, medical care is readily available as long as they remain in the Army. Medical follow-up is possible during this time and arrangements are now being made for a long term study of these individuals following separation from the service. Hospitalization and nursing care are available during the acute and convalescent phases of the illness. The transfer to hospitals in areas of low incidence of rheumatic fever for convalescent care and the subsequent assignment of these individuals to duty for six months at stations in similar areas of low incidence, provide the possibility of residence in low incidence areas for approximately ten to twelve months after the onset of the acute illness.

A frequent problem that occurs during the handling of patients with rheumatic fever is the development of anxiety states with resultant psychosomatic manifestations in many cases, as a result of the patient's knowledge of the serious heart complications of rheumatic fever and the necessity for frequent cardiac examinations, electrocardiograms, and so forth. In the convalescent program this problem has been minimized or obviated by the following measures: (1) appreciation of the problem by the responsible medical officers, (2) proper handling of each patient so as to insure the development of confidence in the physician, (3) a definite plan of explanation and reassurance to the patient, designed to correct erroneous ideas in relation to prognosis of the disease and, particularly, to point out the likelihood of complete functional recovery. This has taken the form of lectures, group psychotherapy, individual conferences, and/or psychiatric consultations where necessary, (4) avoidance of unnecessary examinations and the discussion in the presence of the patient of such findings as cardiac murmurs, prolonged P-R intervals and cardiac enlargement. Where the patient is in possession of such information, explanation and reassurance have proved to be particularly valuable, (5) a physical training program arranged so as to demonstrate to the patient that prior to returning to duty he is able to carry out vigorous exertion without difficulty.

Patients with established valvular defects who are returned to duty receive special consideration in regard to physical training. The tendency to anxiety in relation to the heart condition can be effectively allayed by encouragement to participate in as much physical activity as the individual's cardiac reserve permits. Many individuals with valvular lesions have no manifest loss of cardiac reserve and are capable of as much physical exertion as any normal person. A convalescent patient with a valvular defect who is to be returned to duty participates in the physical training program to the extent that his

permits in the judgment of the responsible medical officer. A rough guide to such an individual's ability to stand vigorous exercise is his demonstrated ability to participate without the development of chest pain, undue dyspnea or fatigue.

The prolonged hospitalization and medical observation necessary for the proper care of rheumatic fever has a tendency in itself to induce anxiety. To avoid this, as soon as the convalescents become fully ambulatory, they are moved from the hospital and housed in barracks under living conditions which approximate normal army life as closely as possible. They are required to adhere to a daily schedule that affords them the same liberties and disciplinary restrictions encountered in normal army duty. Except for periodic medical check-up they are thus removed entirely from a hospital atmosphere. In addition to its effect upon morale this housing plan provides a convenient arrangement from which the details of the physical training and vocational phases of the convalescent program, to be described below, are carried out.

Rheumatic fever has been considered a childhood disease. Information relative to pathogenesis and prognosis of at least the acute phase of this disease has been derived largely from the study of children. The occurrence of acute rheumatic fever in epidemic form in the armed forces, in many cases initial attacks, has focused attention upon acute rheumatic fever as an adult disease. In addition to routine medical care, certain studies are being done regarding the necessity for prolonged inactivity following acute rheumatic fever, the relationship between activity and recurrences, the relationship between early activation and the subsequent development of valvular defects, and the management of persistent streptococcus carriers in patients convalescing from rheumatic fever.

PHYSICAL TRAINING PHASE

The prolonged restriction of activity in the usual case of rheumatic fever necessitated an intensive, graduated program of physical training to insure that each convalescent returned to duty in the highest degree of physical fitness. This is one of the most important aspects of the convalescent program.

After joint symptoms and fever have subsided, if the general condition permits, physical training, in some cases, is started while the patient is still in bed. Mild passive and active bed exercises are used. Where joints have been involved for a long time, special muscle-setting exercises have been helpful.

Physiotherapists and specially qualified physical training personnel are available for this work. Some medical officers prefer to withhold all exercise until the erythrocyte sedimentation rate has returned to normal and the patient gotten out of bed. In all cases, when the patient is ambulatory, mild graduated calisthenics are started on the ward.

These are combined with less strenuous games, such as darts, croquet and shuffle board, as additional exercise is desired.

In the barracks phase of the convalescent program half of the day is devoted to a schedule of carefully supervised, graduated physical training. Calisthenics, close order drill, group games and hikes are the components of the program. The intensity of the various activities is gradually increased so that, prior to returning to duty, the convalescent is exercising on a level comparable to full duty activity. In addition to insuring maximum physical fitness upon return to duty, this program is of value psychologically as an indication to the patient of the extent of his functional recovery from rheumatic fever.

A standardized graduated physical training program is being used for both hospital ward and barracks phases of the convalescent program. Integrated with this program is a group of graduated physical fitness tests which are used, in conjunction with clinical observation, to determine the rate at which the convalescent is allowed to progress to the successively higher levels of physical activity.

This plan provides adequate physical retraining prior to the return of the convalescent patient to duty and ensures that each patient returns to duty in physical condition adequate for the performance of duty in his particular military occupational specialty.

VOCATIONAL PHASE

Rheumatic fever is usually incurred in the first year of an individual's Army experience. For this reason many patients with rheumatic fever have not completed training for a military occupational specialty. Personnel with certain military occupational specialties require reclassification because of rheumatic fever. Both of these groups of individuals, during the ambulatory phase of the convalescent program, are given schooling and/or on-the-job training so that, prior to returning to duty they are classified in an appropriate military occupational specialty. In this way the time available in the convalescent program is used as productively as possible, both for the service and for the individual.

Under this plan vocational training is available to all patients in the convalescent program. In addition to its psychological value in providing occupational therapy for the convalescent patient it offers the opportunity for any specialized training necessitated by possible physical limitations due to the sequelae of rheumatic fever.

CONCLUSIONS

A definitive convalescent program for patients with rheumatic fever has been developed by the Army Air Forces.

The program provides for adequate medical care and follow-up hospitalization and nursing care, convalescent care, physical retraining, schooling, occupational therapy, vocational training, and residence in

an area of low incidence of rheumatic fever for a period of ten twelve months after the onset of the acute illness

FATIGUE AND EXHAUSTION STATES IN THE ARMY AND IN INDUSTRY

JOSEPH L. FETTERMAN, M.D.*

MAJOR, MEDICAL CORPS, UNITED STATES ARMY (RET)

FATIGUE and exhaustion cover a wide field whose boundaries extend from normal tiredness on exertion to acute nervous disorders. Ordinary fatigue is too well known or rather felt to deserve discussion here. We will, however, mention briefly the fatigue reactions occurring in industrial life, then discuss in greater length the more profound exhaustion states such as occur in military life. What causes them, how are they related to neuroses, how can they be prevented or treated?

INDUSTRIAL FATIGUE

Industrial fatigue arises from a single cause or combination of factors such as prolonged hours of work, uncomfortable situations of temperature, humidity, dust, and unfavorable mental reactions. Prolonged exertion is of itself the most common cause of tiredness to the point of decreased output. Sayers¹ cites the experience of British munitions workers who, under the pressure of terrific need, worked seventy-four hours per week. When the working week was later reduced to fifty-five hours, the weekly output did not fall off, rather it was increased by 13 per cent. In some instances production was 10 per cent greater during a month when workers were made to stop work for four ten minute periods during a work day. Within limitations, a reduction in hours of work leads to an increase in hourly output so that the daily output rises (Sayers). Indeed, the fatigue factor of long hours without a rest day and without vacation so reduced productivity that Churchill announced, "If we are to win the war it will be largely by staying powers. For that purpose there must be one day in seven for a rest and as a general rule there must be one week's holiday a year."

But prolonged hours alone do not tell the whole story. The atmosphere both physical and social, is significant. The employee-employer relationship, provisions for safety, adequate rewards, incentives, all determine capacity and output. Again we may quote from Savers "Industrial fatigue is related to environmental conditions and relations with management and fellow workers. These are more important than

physical activity except in the 'heavy' industries that require hard physical labor"

The workmen who dislike the kind of work they are doing, who are in a state of fear and tension because of its hazards, those who accumulate a growing resentment against their employers, such men and women readily become fatigued. Pent-up resentment and unexpressed hostility consume energy, lessen the benefit of rest, lead to earlier exhaustion.

Long hours of work leading to fatigue does not produce ill health. Sayers summarizes an extensive study of the literature on fatigue thus: "Data on fatigue and health show the connection between fatigue and loss of working efficiency and increased accident occurrence but there is little actual proof that long fatiguing periods of work permanently affect efficiency, health, or working capacity." We may interpret Sayers' conclusion to mean that continuous effort may lead to fatigue symptoms. However, these are reversible and the fatigue does not permanently affect health.

CAUSES OF FATIGUE AMONG FIGHTING FORCES

The factors that lead to fatigue in war are more numerous, more prolonged, and far more severe than in industry. Among working men it is one or a combination of prolonged hours, unfavorable environment, and psychologic factors. These same factors, far more disturbing, are present in warfare—and many more besides. The soldier must endure prolonged exertion, is exposed to weakening climate, suffers deprivations of food, of rest, of sleep, lives in a state of uncertainty, frustration, or actual fear. Periods of monotony or of tense worried anticipation are followed by ceaseless noise, long marching, and fighting in which buddies are being killed and his own life is in danger. Thus, the causes of fatigue are usually not single but multiple and their effect, cumulative.

Exertion—Fighting is tough. The soldier must take territory on foot—march in on the enemy. In attack as in retreat he has to hike along, uphill and across stream, in rain and snow and mud, weighed down by a heavy pack. He begins training with a hike of 5 miles, then he hikes 10 miles, then up to 25 and finally 30 miles with a full pack weighing over 50 pounds. During training he may enjoy the refreshing luxury of a rest and even have long sleep afterwards. Not so in combat. Then one day's march may be followed by another march with little or no rest. Picture the plight of the British Expeditionary Force retreating towards Dunkirk. Such a retreat means incessant plodding under bombing to reach the goal of safety. On other occasions soldiers may remain in the trenches for days of continuous firing with little or no rest. Here is a description from Hurst²: "Men who fought six days and nights—they were tired almost to death, and when called on to make one last effort after six days and nights of fighting and marching

many of them staggered like men who had been chloroformed, with dazed eyes, and grey and drawn faces speechless, deaf to words spoken to them, blind to menace about them, seemingly at the last gasp of strength. They had a drunken craving for sleep and slept standing with their heads falling against the parapet." Again let us follow the American foot soldier described so feelingly by Ernie Pyle³ "Their nights have been violent with attack, fright, butchery, and their days sleepless and miserable with the crash of artillery. They are walking 50 feet apart for dispersal. Their walk is slow for they are weary every line and sag of their bodies speaks for their inhuman exhaustion. On their shoulders they carry heavy steel tripods, machine gun barrels, leaden boxes of ammunition. Their feet seem to sink into the ground from the overload they are bearing. They don't slouch. It is the terrible deliberation of each step that spells out their appalling tiredness. Their faces are black and unshaven. They are young men but the grime and whiskers and exhaustion makes them look middle aged."

Outfits who have landed on beaches, as in the Sicilian invasion, keep going for several days and nights without rest or sleep and then perhaps snatch an hour or two hours' rest as they go on and on. It may be two weeks before a soldier can relax for a refreshing night's sleep.

Climatic Factors—The hardship of soldiering is not alone the expenditure of muscular energy, it means also endurance of unfavorable climate. Picture the soldier from the south who made an amphibious landing in Attu in the Arctic, through cold waters, marching against a misty cold wind, and sleeping on freezing ground. Think of the many Americans, some from Maine and Michigan, who are stationed in the tropics, in Panama, in North Africa, in the islands of the South Pacific, the deserts of Iran, or tropical India. Such a soldier must endure the sands of the desert or the sweaty steam of the jungle at temperatures of 110° to 120° F, or even 140° F. An officer of engineers who helped construct a road through Iran for the shipping of supplies to Russia insists that he saw the thermometer reach 185° F in the sun at noon. He considered 120° to 140° F as common. It is no wonder many of our soldiers lose 20 to 30 pounds when they are in the tropics.

Deficiencies (In a general sense)—The human body to be comfortable and efficient needs rest and materials for replenishment. Deprived of rest, lacking sufficient chemicals, wanting adequate vitamins and calories, a person becomes uncomfortable, loses the capacity for first grade performance, and may develop sickness—if the defect is not corrected.

Despite the excellent precautions of our War Department, soldiers cannot escape deficiencies. First is lack of sleep. In warfare a soldier does not choose his bed and then sleep in it. His abode may be the ground, a foxhole, amidst heat and smell. Booming artillery jars him

Enemy planes return night after night, and the warning siren means a hurried run in darkness from the bed or sleeping bag into the fox-hole. Or the bitter cold of Iceland finally penetrates through the warm sleeping boots to awaken him, while he who is in the jungle cannot fall asleep because of the heat or insects.

Though our soldiers are among the best fed troops in the world, there are periods of unavoidable dietary deficiency. The men fighting in the desert lose chlorides from sweating and may go without sufficient water. Those in the front lines may be limited to canned rations and at times an insufficient number of them. One captain told of being several weeks in the front lines of Guadalcanal with a minimal amount of water so that he and his men drank from any pool or stream and subsisted upon one can of food daily. (The prescribed number was three or more cans in twenty-four hours.) He lost 30 pounds in six weeks. A corporal who was also in Guadalcanal, during his weeks in the front lines slept poorly, ate little, and also had diarrhea. When he reached the station hospital in a weak and nervous state his scaly skin and shiny tongue gave evidence of avitaminosis.

Thus the soldier is exposed to deficiencies of rest, of food, and may likewise be weakened by disease (infections from insect bites, diarrheas, malaria, and so forth).

Psychologic Factors—Coupled with the physical hardships of warfare is a succession of situations disturbing to the psyche. From the beginning of his training the soldier may be irked by the restrictions and regulations, troubled by unsolved and recurring problems at home, distressed by frustrations, emotionally disturbed by the preparations for combat. Some soldiers, previously timid, peace-loving civilians, may find it most trying to learn to shoot, are sensitive to the noise of artillery. Yet most of our men pass through this period of basic training and of maneuvers successfully. But the scene changes when the soldier has been transported to the zone of combat and has landed on enemy soil. In combat he is exposed to horrors and hardships that try men's souls (Paine). He is subjected to incessant noise, the sharp sound of rifle bullets, the boom of artillery, the shrieking siren of dive bombers. He must sit in the foxhole or march forward in the face of noise which spells death. He sees wounded and bleeding buddies, he witnesses death of friends and foe. Ahead of him behind a clump of trees is a sniper, or in the house on the hilltop is a deadly 88 mm gun spouting shells which explode dangerously near.

Confronted with these hazards every man is afraid. His training compels him to control the usual instinct of escape and to become an automatic machine which marches and shoots. Yet when the soldier doubts the quality of his arms, lacks complete faith in his leaders, fears that his platoon or company has lost contact with the main body and is being surrounded, then that soldier loses confidence, becomes fearful or even panicky. His already depleted energy is further abruptly

reduced. Fear exhausts more than exertion. It utilizes the nerve pathways, the metabolic processes, the muscles, as does constructive purposeful activity. Yet the indecision leads to energy wasted in motion and in inhibition, as when racing a motor of a car held back by unreleased brakes. Overwhelming fear leads to rapid heart action, to rising blood pressure, to outpouring of adrenalin counteracted by "frozen" muscles or expressed by tremors. Not only muscles but thinking processes seem paralyzed by doubt and fright.

If among industrial workers psychologic factors, such as interest in the job, relationship to personnel, rewards for work are important, they are even more so among soldiers in combat. It is well known that soldiers marching to attack are less fatigued than when they retreat even though the distance and terrain be identical. The failure of the mission meant fatigue. A major observed in a certain theater of operations that the number of patients referred into the hospital with acute combat fatigue, labeled "exhaustion" because fatigue was a prominent feature, was fewer during the period of successful attack than when our forces were in danger of being surrounded. In combat, fatigue results not from one item but the combination of exertion, deficiency and psychologic factors. The psychologic factors especially of fear, the depletions resulting from deficiencies, and the excessive expenditure of energy lead to a variety of symptoms.

THE MAN WHO IS FATIGUED

Before reviewing symptoms let us consider the man. For our practical concern as physicians is not with fatigue, it is with fatigued men and women. Not the exposure alone but the caliber of the exposed determines the degree of symptoms. In our discussion we may take up the physical and the psychologic aspects separately, though in life they are inseparable.⁴

There is a muscular quotient as there is an intelligence quotient. The Army gives every inductee an intelligence test that enables a separation into five classes from Group I (superior intelligence) to Group V (lowest group). We utilize such classification in duty assignments. Yet men are also different as to their muscular and motor power. The bodily processes—metabolic, circulatory, muscular—the sum total of which is action and stamina, are different from man to man. We vary in the capacities of our backs as in the functions of our brains. Some men can march further, lift more, and possess the resiliency to regain well being after exertion. Others fatigue more quickly and take a longer time to recuperate. Not only is there an innate difference but also age, body build and of course training may modify this difference. The Army took cognizance of the importance of age in the selection of younger men for combat only. So also in picking troops for hot climates, Circular Letter SGO No. 119⁵ advises the selection of ' wiry men between the ages of twenty and thirty.

The psychologic factors depend upon the personality makeup. Some men possess self-confidence, accept their assignments cheerfully and endure hardships with the average attempt to dissipate dissatisfaction by humor and griping. Others start out in life with the minus sign of being tired out because of self-pity, worry, ideas of being mistreated. Energy thus expended in doubt and distrust is energy wasted. He is most fatigued who is tired of it all.

We may take a detour from our discussion of personality and fatigue to glance at the reactions of soldiers injured in combat. The decisive factor is the personality more than the injury or loss. Recently I lived with a group of amputee soldiers and officers—men wounded in combat and suffering the loss of an arm, leg or several members. The reactions of a lieutenant were typical. "Sure, I lost both hands in the grenade explosion, but I got to make the best of it. I have learned to use the prostheses (grasping device), I can write with a pencil, can type, eat, and I am learning to do more every day. I have a tough time buttoning a shirt, and tying the knot of my tie, but I'll master those. My real ambition is to learn to shoot—I love quail hunting." This officer showed no self-pity, was not lost in his tragedy but was studying salesmanship and trying to rise above his defect. So, too, men differ in their later reactions to fatigue.

As we consider symptoms and clinical states, let us keep in mind not only the stress of industry and warfare but also the qualities of the man subjected to the stress.

SYMPTOMS AND SYNDROMES

Guttman and Rimolditt⁶ include the following items under the symptoms of and meaning of fatigue. The output curve of effort diminishes, psychologically, there is an attitude of boredom and loss of interest, unpleasant sensations locally such as aches and pains, and the emotional tone tends towards depression, with loss of initiative, slowness, indecision and a sense of incapacity. All of us are aware of the local distress of fatigue, tired sore eyes with blurring of vision after prolonged reading, sore, weak, aching muscles after a long march. Profound depression or apathy occurs after greater exhaustion. Such apathy was illustrated by the experience of a British officer, taken captive in the retreat to Dunkirk. He had marched with his men day and night, taking little time for rest, and subsisting on little or no food. After several days of such exhausting march he and his men were surrounded by the enemy. He surrendered automatically, too tired to observe, too tired to care. He could barely hold his head up, barely lift his feet as he trudged to a vehicle and later was transferred to a train. He took no notice of where he was being moved, fatigue made him almost entirely oblivious to recognition of time and place. He didn't seem to care. After he had rested in the prison camp and after he was refreshed by food, he became keenly conscious of his surround-

ings. He took careful note of the place, its guards, its weaknesses, and began to plan an escape. Within a short time he succeeded in the escape.

Fatigue is usually accompanied by indifference or apathy, yet the mental state will depend upon the degree of exertion and upon the nature of the cause. There is subjective grading from saturation to exhaustion, from staleness to complete inability to go on.

Likewise fatigue occurring in play may be pleasurable, in work, painful. Success or failure are important. The two partners of a foursome who come back joking and cheerful after eighteen holes are the victors, the defeated drag in, more tired. Success affords exhilaration, failure, exhaustion.

Thus, the direct effect of fatigue is local discomfort, intellectual dulling towards inattention and apathy, plus a general decrease in efficiency and performance. Such symptoms apply chiefly to industrial fatigue. Consider the soldier whose fatigue has resulted from a combination of exertion, deficiency, and fear. The soldier may exhibit symptoms not as a direct result of exhaustion but indirectly as escape mechanisms when exhaustion has broken the wall of personal defense. Like sandbags protecting the banks of the Mississippi against flood, so is the self-control that each person has built for himself. From infancy onwards we have acquired the self control that enables us to restrain cries and tears, to check trembling and running. Army training adds to this wall of self-control so that we maintain our positions despite the sound and recoil of fire, can distinguish between the true danger of a near bomb burst from the distant roar of artillery. This enables the soldier to go forward, to appraise danger and face it, to dismiss thoughts of terror, to distinguish images from reality.

Fatigue and exhaustion remove this wall of self control, as time and the elements wear away the sandbags of protection. Some soldiers, like a quiet river, move lethargically, while the pent-up emotions of others sweep over all bonds and release all manner of reactions. Like a raging river torrent which inundates the land, the emotions run riot, one cries, the other laughs, one trembles, wanders in confusion. The type of syndrome will reveal the interplay between exhaustion, the experiences, weaknesses, and strivings of the individual. Truly, every man has his breaking point, but the direction and extent of the break vary. Like glass exposed to excessive pressure which may crack in one or two main lines splinter in many directions, or blow to bits, so the reaction to exhaustion differs. In some the upset is abrupt, in others it is gradual, passing through prodromal stages toward the phase of advanced symptoms. Kubie⁷ lists some of the early symptoms (signal of incipient breakdown) as sleep disturbances and nightmares, daytime startle states, abstracted manner, change in voice, change in daily habits, and in personality. As the condition continues, more pronounced syndromes appear.

The disorders may affect the motor apparatus chiefly the

organs, or the mental control. Thus, tremors or paralysis may dominate the picture, or a series of autonomic derangements, tachycardia, nausea, vomiting, diarrhea, represent the reaction, or acute confusion, manic behavior, stupor may set in. Braceland and Rome⁸ list the symptoms of severe exhaustion in the Naval service as follows

- 1 Heightened irritability (startle response, night terrors, vigil state)
- 2 Autonomic nervous symptoms (tachycardia, gastrointestinal upsets, sweating)
- 3 Fatigue—a diminished capacity for work
- 4 Personality changes—depression, anxiety, panic, apathy, confusion

Among the acute nervous reactions of British soldiers in the Middle East are mentioned "shivering, stuporous states, hysterical manifestations, like deaf mutism, paralysis, or blindness"
